In ICD-10, the term 'dissociative convulsions' is used to refer to paroxysmal episodes of behaviour that resemble epileptic seizures and which are believed to be due to unconscious psychological processes. These episodes may imitate any form of epilepsy and the term *dissociative seizures* is probably more accurate because convulsions are often not present. Dissociative seizures are distinguished from factitious disorder on the grounds that the latter represents a wilful, conscious attempt to simulate illness for reasons that are understandable in terms of the individual's psychological state. Factitious disorder is in turn differentiated from malingering (not actually a medical diagnosis), in which illness is simulated to achieve some practical gain (e.g. financial compensation, avoidance of criminal responsibility or military service). In practice, the distinction between these three entities can be very difficult. Conscious fabrication may sometimes be suspected but a diagnosis cannot be made confidently unless the patient admits deliberately enacting the symptoms, or is 'caught out' by some form of covert surveillance (not, however, recommended). Even then, there is potential overlap: what begins as unconscious may become deliberate over time, and vice versa. Another difficult area concerns the boundaries of malingering: in many countries there is considerable financial reward (in the form of social security benefits) attached to the sick role, and this obviously represents a significant practical gain. Judging motivation is every bit as subjective, and difficult, as assessing the extent to which symptoms are under voluntary control.

By consensus most episodes are regarded as unconsciously motivated and therefore dissociative. However, some clinicians are not persuaded (Slavney 1994). The distinction between dissociative and factitious disorder implies a dichotomy that is undoubtedly an oversimplification. The two are better thought of as opposite ends of a spectrum of

conscious awareness, with 'self-deception' occupying the middle ground. The concept of self-deception, which at a trivial level most people can relate to (e.g. how young/slim we look, procrastinating about a work deadline), provides a useful paradigm for understanding unconscious mechanisms and how subjective experience, and even quite complex behaviour, are prone to influences that are not always fully conscious, even in healthy individuals. Three observations provide some objective evidence that dissociative seizures are, at some level, unconscious: (i) most patients are compliant with antiepileptic drugs before the correct diagnosis is made; (ii) when patients are admitted for telemetry, the majority have a seizure in a setting which they must surely recognise involves sophisticated monitoring; and (iii) the seizures are usually a poor imitation of epilepsy. None of these points is by any means conclusive, but if deception is involved it is of a kind that eludes simple understanding.

Before leaving the subject of definition and nosology, it must be acknowledged that there is no consensus about what these episodes should be called. Terms such as 'pseudoseizures' and 'hysterical seizures' are seen as pejorative and have largely been abandoned. Others like 'non-epileptic seizures/events', 'non-epileptic attack disorder' and 'psychogenic non-epileptic seizures' are widely used but appear to define the condition by what it is not, and may therefore be interpreted by patients as suggesting that 'the doctors think I don't have epilepsy but they don't know what I've got'. Some of these terms are also used ambiguously. For example, 'psychogenic non-epileptic seizures' may be used to refer to dissociative seizures alone or to the group of psychiatric disorders (including panic attacks, psychosis, temper tantrums) that can be mistaken for epilepsy. Likewise, 'non-epileptic seizures' is often used to refer to the range of conditions, organic and otherwise, that may be mistaken for epilepsy, but on other occasions may be used as a form of shorthand to denote dissociative seizures. The term *functional seizures* overcomes many of these objections, is acceptable to patients (Stone *et al.* 2003) and also has the advantage of remaining neutral with respect to any assumptions about conscious or unconscious processes. However, it has not found widespread acceptance so far.

Demographic features

The clinical problem of dissociative seizures has generated a substantial literature and there have been a number of reviews (Krumholz 1999; Gates 2002; Reuber & Elger 2003; Mellers 2005). Approximately one in five patients referred to specialist centres for evaluation of apparently intractable epilepsy are found to have dissociative seizures. A similar proportion has also been reported in a community-based survey of new-onset seizure disorders (Kotsopoulos *et al.* 2003). Over two-thirds of patients are female. Seizures typically begin in the late teens or early twenties, but there is a

wide range. In a minority (less than 20%) a history of epilepsy precedes the onset of dissociative seizures.

Unfortunately, there is often considerable delay in recognising the disorder and it is common for seizures to have been present, and treated as epileptic, for over 3 years before diagnosis. This of course represents a missed opportunity for appropriate treatment. In addition, patients are exposed to significant iatrogenic risks including antiepileptic drug toxicity, teratogenic risk and the risk, in up to 10%, of receiving emergency treatment for supposed 'status'. Unfortunately, the longer the patient and family live with an incorrect diagnosis of epilepsy, the more entrenched their adaption to a life of disability and the less likely that treatment will be effective.

Dissociative seizures must be distinguished from epilepsy and other paroxysmal disorders of consciousness and neurological function. The clinical features of dissociative seizures, and the role of special investigations are therefore detailed in the following sections on assessment and differential diagnosis.

Psychiatric assessment: aetiological formulation

Psychiatric assessment aims to detect any comorbid psychiatric disorder and to determine likely aetiological factors. Table 6.11 lists predisposing, precipitating and maintaining factors that may be relevant. Many of the factors are common to other somatoform disorders and indeed up to 80% of patients with dissociative seizures have a history of previous unexplained medical presentations (Bowman & Markand 1996). Variable rates of psychiatric comorbidity, including personality disturbance, depression and anxiety, have been reported. Adverse or traumatic experiences, particularly in childhood, are a common underlying theme. An association with sexual, physical and emotional abuse has been highlighted but other traumatic experiences or situations that foster enduring low self-esteem, for example being bullied at school or unrecognised learning difficulties, or a more general association with poor family functioning, may be equally important. Abnormal personality traits, dysfunctional coping styles and putative somatising or dissociative traits may be a consequence of adverse experiences at a stage of development when personality attributes are formed. Biological factors, including genetic influences on personality, are plausible but as yet hypothetical. None of these features, however, is unique to patients with dissociative seizures; they are seen in patients with other psychiatric disorders and other somatoform presentations. Why some individuals exposed to grossly abnormal experiences develop psychiatric disorder but not others, and what determines the form the illness takes, is not understood.

Triggers for the onset of the disorder are often not apparent, but an increased incidence of adverse life events in the year prior to onset has been reported. Sometimes the clinical history strongly suggests that the initial event may have been

Table 6.11 Predisposing, precipitating and maintaining factors in dissociative seizures. (Modified from Binzer *et al.* 2004 with permission.)

	Biological	Psychological	Social
Predisposing	Learning difficulties ?Genetic influence on personality ?Biological effect of early adversity on CNS development	Perception of childhood experience as adverse Somatising trait Dissociative trait Avoidant coping style Personality disorder Mood disorder	Adverse (abusive) experiences in childhood Poor family functioning Traumatic experiences in adulthood Modelling of attacks on others with epilepsy
Precipitating		Perception of life events as negative/unexpected Acute panic attack/syncope	Adverse life events
Maintaining		Perception of symptoms as being beyond personal control/due to disease Agoraphobia: avoidant and safety behaviour Angry/confused/anxious reaction to diagnosis	Angry/confused/anxious reaction of carers to the illness and to medical encounters Fear of responsibilities of being well/benefits of being ill

a panic attack or an episode of vasovagal syncope. Once the disorder is established a number of maintaining factors become important. An agoraphobic pattern of avoidant and safety behaviour may serve to perpetuate anxiety about seizures, which in turn makes them more likely. Patients typically receive conflicting advice from many doctors and may encounter unsympathetic reactions in a variety of medical settings, all of which contribute to their anxiety, confusion and anger. Finally, for some individuals at least, the benefits of the sick role may provide an acceptable alternative to the responsibilities of healthy life, and carers, unwittingly or otherwise, may play an important role in perpetuating disability. The stigma attached to mental illness undoubtedly has an important role in shaping the medical presentation of somatoform disorders and contributes to the reluctance some patients have in accepting psychiatric treatment.

There is no widely agreed model for dissociative seizures. As already mentioned, studies of underlying aetiological factors reveal much that is common to other somatoform disorders. Dissociation can be thought of as a psychologically mediated, altered state of awareness or control over neurological function. It encompasses a range of mental processes including normal phenomena, such as focused and divided attention, as well as pathological states involving perceptual, cognitive and motor function (see Holmes *et al.* 2005). Dissociation may be encountered as an acute response to trauma, as chronic persistent symptoms (e.g. amnesia or paresis) or as recurrent paroxysmal events in dissociative seizures. Some two-thirds of patients with dissociative seizures report symptoms of autonomic arousal preceding their seizures (Goldstein & Mellers 2006). A dissociative response to arousal triggered by perceptual or cognitive cues, perhaps related to previous traumatic experiences in a manner akin to post-traumatic stress disorder (Ehlers & Clark 2000), is thus one possible mechanism. The pathophysiological basis of disso-

ciation is unknown. While it cannot be assumed that the processes underlying normal dissociative phenomena are active in pathological states, as a hypothesis this provides a useful starting point for further investigation. The concept of dissociation, and in particular the assumption of some continuity between normal and abnormal dissociative states, also provides a very useful model for discussing dissociative seizures with patients and carers.

The treatment of dissociative seizures is discussed under Treatment of psychosis, later in chapter. Reuber and Elger (2003) have reviewed naturalistic outcome studies. Overall, seizures persist for over 3 years in approximately two-thirds of patients. Even if seizures remit, patients tend to remain unemployed and dependent on social security. By far the most important predictor of outcome, as in other somatoform disorders (Couprie *et al.* 1995), is a short duration of illness at the time of diagnosis.

Assessment and investigation

It has often been said that epilepsy is a clinical diagnosis. A carefully elicited history and particularly an eyewitness description are the cornerstones of assessment, and diagnosis is said to be straightforward in expert hands (Chadwick & Smith 2002). Yet outside specialist settings, and perhaps even within them, diagnostic errors are frequent. In one study of patients referred to an epilepsy specialist, 26% of those already taking antiepileptic treatment had been misdiagnosed (Smith *et al.* 1999). Such mistakes have serious consequences. Firstly, they represent a missed opportunity for appropriate treatment. The two most common differential diagnoses, syncope and psychogenic attacks, account for the overwhelming majority of diagnostic errors. While most cases of syncope are vasovagal and have a relatively benign course, failure to recognise syncope due to cardiac arrhythmia has potentially fatal consequences. In the case of

dissociative seizures, a missed diagnosis represents a lost opportunity for intervention early in the course of the disorder, when it is most effective. Secondly, misdiagnosis incurs the risks of inappropriate treatment, including drug toxicity and the hazards of emergency interventions for supposed status epilepticus. Patients misdiagnosed with epilepsy will also needlessly suffer driving and occupational restrictions. Finally, there are implications for health-care resources. Smith *et al.* (1999) estimated the cost of misdiagnosed epilepsy to the National Health Service to be around £125 million pounds annually. Overall, the consequences of a mistaken diagnosis probably outweigh the small risk of delaying treatment in epilepsy (Chadwick 1994; Manford 2001). A trial of treatment is seldom justified (see also discussion of injury and sudden death in epilepsy in Treatment, later in chapter).

The first task of assessment is to distinguish between epilepsy and other causes of transient loss of consciousness or paroxysmal neurological disturbance. Epileptic seizures are brief stereotyped disturbances of neurological function that may involve mental, autonomic, sensory and motor features. While the clinical manifestations of epileptic seizures are protean, the *sequence* of events will be similar from one episode to the next and will conform to a relatively small number of well-established patterns. These patterns, set out in the ILAE classification of seizures, provide the key to recognising an event as epileptic. If attacks are judged to be epileptic, seizures that have been provoked by some extrinsic factor must be differentiated from those likely to recur. Once the type of seizure has been recognised, clinical features and further investigation will help identify underlying aetiology and the epilepsy syndrome.

Clinical assessment

Are the seizures epileptic?

An eyewitness description should always be sought and will often provide the most important clues to diagnosis. The patient and informant need to be questioned closely about events before, during and after seizures. It is helpful to ask at the outset how many types of attack there are and then to determine the sequence of events for each type. The relationship between different types of seizures must also be established. For each phase of symptoms three questions are important: what happens, how long does it last and is it usually the same? Prodromal symptoms may precede the seizure by hours. The patient should be asked about any 'warning' at the onset of the attack before enquiry is made about specific types of aura. Epileptic aura usually last less than a minute or two. Symptoms preceding syncope may also be brief, but migrainous aura typically evolve more slowly. Does the patient lose awareness and at what point? It is important to obtain an informant history even when patients say they are aware throughout their seizures. Occa-

sionally, it becomes clear that consciousness is impaired only after speaking to an eyewitness. Equally, when patients say they are unaware throughout their seizures, this should be checked with an informant. If someone tries to assist or speak to the patient in the middle of an attack, what happens? Does the patient respond? Does seizure activity change or stop (suggesting dissociative episodes)? The informant must be asked specifically about the subtle motor features of partial seizures as these may be very helpful diagnostically and are often not reported spontaneously. Examples include oral automatisms, facial twitching, dystonic posturing and the repetitive fumbling hand movements associated with gestural automatisms. Where the history suggests generalised seizures, it is important to check carefully for the presence of aura (which will suggest secondarily generalised seizures) and other generalised seizure types, specifically absences and myoclonic seizures which may otherwise go unreported. Absences may be put down to daydreaming or inattentiveness, and myoclonic jerks dismissed as clumsiness first thing in the morning. If there is a fall, it is important to establish if there is a rigid (tonic) crash to the ground, a sudden loss of tone with collapse and pallor (suggestive of syncope), or a 'swoon' (suggesting psychogenic aetiology). Careful attention needs to be paid to the nature, progression, timing and distribution of any convulsive movements. In a tonic-clonic seizure there will be a tonic phase of general stiffening followed by fine, symmetrical and synchronous clonic movements that increase subtly in amplitude and slow down as the seizure comes to an end. Thrashing, flailing, combative movements are unusual in epilepsy and will strongly suggest dissociative seizures, especially if they last for more than a minute or two. The most important feature of the recovery phase is how quickly normal function is restored. Slow recovery over several minutes with confusion is typical in epilepsy. However, abrupt recovery is seen after absence seizures and in some patients with FLE. Rapid recovery without confusion is characteristic of syncope and is seen in many dissociative seizures. Postictal tiredness, confusion and headache do not help differentiate dissociative and epileptic seizures. A clear description of postictal dysphasia will sometimes help identify partial onset epilepsy. Incontinence and injury are relatively non-specific: they are common in epilepsy but not uncommon in syncope or dissociative seizures. The type of injury may be a more helpful diagnostic clue. Recurrent dislocation of the shoulder (especially posterior dislocation) and vertebral body fractures almost always suggest epilepsy. Tongue-biting in epilepsy usually involves the lateral aspect of the tongue. In dissociative seizures, bites are more commonly to the tip of the tongue, the cheek or the lips, and carpet burns to the face or limbs are also common. It is important to examine the tongue if a history of bite injuries emerges: a severely scarred tongue is seldom seen in non-epileptic presentations. It is also important to ask if attacks occur in sleep and, if so, at what stage of the night and whether

such attacks are the same as daytime episodes. Patients with dissociative seizures will report attacks during sleep as often as patients with epilepsy, but ictal EEG recordings will establish that, in dissociative seizures, the patient wakes before seizure onset (Duncan *et al.* 2004). Attacks occurring only at night will raise the possibility of a parasomnia. The timing of attacks and any circumstances that seem to be associated with a greater likelihood of their occurrence should be noted. Seizures occurring first thing in the morning after waking are characteristic of some syndromes of idiopathic generalised epilepsy. Situational triggers are probably more common in syncope and dissociative seizures than in epilepsy.

Differential diagnosis of epilepsy

Syncope

Syncope refers to a transient loss of consciousness caused by a sudden disruption of global cerebral blood flow (Table 6.12) (Mathias *et al.* 2001; Soteriades *et al.* 2002; Fitzpatrick & Cooper 2006). An atonic fall, marked pallor and rapid recovery are the core clinical features. *Vasovagal syncope* is by far the most common form and is experienced at some stage by up to half the population. Recurrent episodes are less common but still account for the majority of syncopal presentations to seizure clinics. Episodes occur when the patient is standing and emotional triggers are usually obvious. Common examples include receiving an injection or having blood taken, witnessing a distressing event or suffering pain or injury. There is often an agoraphobic flavour to the circumstances of the attack, with patients reporting an urgent

need to escape from crowded, enclosed and hot situations. Less commonly, syncope may be triggered by micturition, defecation and activities involving the Valsalva manoeuvre. Vasovagal syncope is usually identified by the combination of an emotional trigger and the characteristic symptoms of *presyncope* (Brignole *et al.* 2004). These include light-headedness, a feeling of detachment, visual blurring, altered hearing with a sense of noises receding and sometimes tinnitus, profuse perspiration (described as a 'cold sweat') and nausea (which may have a rising epigastric quality) (Sheldon *et al.* 2006). To the observer there is conspicuous pallor ('ashen' or 'deathly white') and a flaccid crumple to the ground brought about by a sudden loss of muscle tone. Consciousness is lost for a matter of seconds only and full alertness returns quickly. During the period of unconsciousness, muscle jerking is evident in 90% of cases when episodes are induced experimentally (Lempert *et al.* 1994) and will be reported by some 15% of informants (Sheldon *et al.* 2002). This takes the form of irregular myoclonic movements that are typically multifocal, asynchronous and asymmetrical. Incontinence and injury, including tongue-biting, are less common than in epilepsy but are reported.

Presyncopal symptoms are much less helpful in identifying other forms of syncope. Syncope due to arrhythmias may be preceded by palpitations but in most cases there are no warning symptoms of any kind. A family history of early cardiac death and a personal history of cardiac disease should raise suspicion. Syncope associated with exertion raises the possibility of structural cardiac disease and requires urgent investigation, although most cases will prove to be vasovagal. *Orthostatic syncope* occurs when rising from a recumbent to a standing position and presyncopal symptoms are often absent. Drugs are a common cause, but autonomic failure may be due to neuropathy or degenerative neurological disease. Carotid sinus hypersensitivity, which presents as syncope triggered by neck pressure (head turning, tight collar), is believed to be a common cause of reflex syncope and falls in the elderly (Humm & Mathias 2006; Kerr *et al.* 2006). Syncope precipitated by upper limb exercise will suggest a vascular steal syndrome. Intermittent obstructive hydrocephalus, caused by space-occupying lesions in the third ventricle, may present with headache and episodes of sudden loss of consciousness which are syncopal and secondary to brainstem compression.

The differentiation of epilepsy and syncope is further complicated by the fact that partial epileptic seizures may rarely cause syncope. Sinus tachycardia occurs in at least two-thirds of partial seizures and is probably of no consequence. However, ictal bradycardia is potentially of great importance. It is believed to be rare, occurring in less than 1% of partial seizures (Zijlmans *et al.* 2002) but is probably under-recognised (Tinuper *et al.* 2001). Ictal bradycardia and asystole may lead to syncope during the seizure, which can be mistaken for secondary generalisation (Rossetti *et al.* 2005).

Table 6.12 Causes of syncope. (Adapted from Brignole *et al.* 2004 with permission.)

Neurally mediated (reflex)

Vasovagal: fainting following a distressing experience
Situational: micturition, defecation, Valsalva, eating, etc.
Carotid sinus hypersensitivity

Orthostatic

Autonomic dysfunction
Complex autonomic dysfunction, e.g. multisystem atrophy
Autonomic neuropathy, e.g. diabetes, amyloid, alcohol related
Drugs, e.g. antihypertensives, diuretics, alcohol

Volume depletion

Cardiac

Arrhythmias

Tachyarrhythmias, e.g. ventricular tachycardia, supraventricular tachycardia, long QT syndrome
Bradyarrhythmias, e.g. atrioventricular block, sinus node disease
Structural, e.g. valvular disease, hypertrophic cardiomyopathy, ischaemic left ventricular disease, left atrial myxoma, pulmonary embolism

Other

Vascular steal syndromes, e.g. subclavian steal syndrome

Table 6.13 Comparative semiology of dissociative and epileptic seizures. (Adapted from Mellers 2005 with permission.)

	Dissociative seizures	Epileptic seizures
<i>Helpful features</i>		
Duration over 2 minutes	Common	Rare
<i>Motor features</i>		
Gradual onset	Common	Rare
Fluctuating course	Common	Very rare
Eyes closed	Common	Rare
Thrashing, violent movements	Common	Rare
Side-to-side head movement	Common	Rare
Asynchronous clonic movements	Common	Very rare
Pelvic thrusting	Occasional	Rare
Opisthotonus, <i>arc de cercle</i>	Occasional	Very rare
Automatisms	Rare	Common
Weeping	Occasional	Very rare
Recall for period of unresponsiveness	Common	Very rare
<i>Unhelpful features (often misinterpreted as evidence for epilepsy)</i>		
Stereotyped attacks	Common	Common
Incontinence	Occasional	Common
<i>Injury</i>		
Biting inside of mouth	Occasional	Common
Severe tongue-biting	Very rare	Common
Nocturnal occurrence ('in sleep')	Common	Common

Figures for frequency of these features are approximate: common, >30%; occasional, 10–30%; rare, <10%; very rare, <5%.

Dissociative seizures

The distinction between epilepsy and dissociative seizures has received a great deal of attention in the literature (Reuber & Elger 2003; Mellers 2005). Some useful features, and others that are often misinterpreted as suggesting epilepsy, are listed in Table 6.13. No single symptom or sign discriminates dissociative and epileptic seizures with complete certainty. Overall, the clinician must be familiar with the clinical forms epilepsy may take, and it is any variation from these patterns – an atypical sequence of events – that raises the possibility of dissociative seizures (Meierkord *et al.* 1991). The most useful distinguishing characteristics of dissociative seizures are probably long duration, eye closure, fluctuating motor activity, and recall following a period of unresponsiveness, especially if there were associated bilateral convulsive movements. A prolonged period (greater than 5 minutes) of motionless unresponsiveness (from which the patient recovers) almost never has an organic cause. Dissociative seizures are often accompanied by symptoms of arousal, including hyperventilation, peripheral paraesthesiae, dry mouth, palpitations and perspiration (Goldstein & Mellers 2006) and there is therefore some overlap with the symptoms of pre-syncope. These symptoms may precede the seizure or be noticed only on recovery. Sometimes hyperventilation will only be apparent from an eyewitness description. Patients

typically deny emotional symptoms during their attacks, reporting instead symptoms of derealisation, including feeling 'cut-off' and in 'their own world'. Emotional triggers are also usually denied. A relationship with stress may be apparent, at least to eyewitnesses and the clinician if not to patients themselves, but precipitation by stress is also common in epilepsy, syncope and migraine. An agoraphobic pattern of avoidant behaviour is more commonly associated with dissociative seizures than with epilepsy.

Patients with dissociative seizures often have attacks at clinic appointments or in accident and emergency departments, and a carefully conducted examination during a seizure is invaluable. Video recordings of seizures obtained by witnesses (often these days with a mobile phone) may also be extremely helpful. The key points to note on observation are the timing and distribution of any motor activity and whether the eyes are closed. Prolonged violent thrashing movements that fluctuate over the course of the seizure will suggest dissociative disorder. If clonic-like movements are present, careful observation will be required to determine if these are regular and synchronous in each limb (as in epilepsy) or not (suggesting dissociative seizures). On examination, the clinician should establish whether patients are unresponsive by calling out to them. Inflicting painful stimuli is not helpful and ethically questionable. A simple test to

establish avoidance of a (mildly) noxious stimulus is to hold the patient's hand over his face and drop it: during a dissociative seizure, on the second occasion this is done, the patient may be seen to control the movement so that the hand falls to one side. If the eyes are shut, an attempt to open the eyelids will usually be met with some resistance in dissociative seizures. If the eyes are open, two additional tests may be helpful. The first involves rolling the patient on to his side. In patients with dissociative seizures the eyes will often be deviated to the ground. If this is the case, the patient should be rolled on to the other side to see if the eyes are still directed towards the ground, the so-called Henry and Woodruff sign (Henry & Woodruff 1978). A second useful test is to hold a small mirror in front of the patient and look for evidence of convergent gaze and fixation on the reflection. This procedure will also often stop the seizure. Following a generalised tonic-clonic seizure the corneal reflex will usually be absent and plantar responses extensor. Pupils will be unresponsive to light in organic states of impaired consciousness.

Paroxysmal neurological disorders

Paroxysmal symptoms occurring as part of other psychiatric disorders may be mistaken for epilepsy. The most common problem concerns panic disorder (see Epileptic aura, earlier in chapter). The brief stereotyped nature of affective and perceptual epileptic aura, together with the presence of impaired consciousness and other epileptiform semiology, mean that distinguishing these ictal presentations from primary psychiatric disorder (panic disorder, psychosis, derealisation disorder) is usually straightforward. The rare occurrence of simple partial non-convulsive status with prominent experiential symptoms (aura continua) is discussed under Non-convulsive status epilepticus, earlier in chapter. Juvenile absence epilepsy may present with academic failure and complaints of inattentiveness at school that might raise the possibility of attention deficit disorder.

Other paroxysmal neurological disorders are listed in Table 6.14 and discussed below.

Transient ischaemic attacks. The clinical features of transient ischaemic attacks typically involve a loss of function (as

distinct from the positive phenomenology of epilepsy) and are usually of relatively prolonged duration. Impaired consciousness is not a feature of neocortical ischaemia but may occur in vertebrobasilar ischaemic episodes.

Classical migraine with aura followed by headache, photophobia and nausea seldom causes any diagnostic difficulties. However, migrainous aura may occur in isolation (acephalgic migraine or migraine equivalent). Visual disturbances are the most common form of aura, but sensory, motor, speech and cognitive disturbance, including clouding of consciousness, are seen occasionally (Al Twajiri & Shevell 2002; Young & Silberstein 2006). The visual aura of migraine typically involve scintillating, monochromatic, zig-zag lines that evolve slowly over tens of minutes. In contrast, visual aura in occipital lobe epilepsy are of sudden onset, brief duration and of coloured, round, often moving shapes. Overall, the characteristic pattern of symptoms, slow onset and gradual resolution help identify the various presentations of migraine.

Vertigo is an illusion of rotation due to a disorder of the vestibular system (Halmagyi 2005). True vertigo must be distinguished from symptoms of dizziness and light-headedness, which are non-specific and often reported as prodromal symptoms in epilepsy, and in association with syncope and dissociative seizures. Vertigo has been described with frontal and parietal seizures but is such an uncommon feature of epilepsy that it should immediately call other diagnoses to mind (Altay *et al.* 2005). The underlying disturbance of vestibular function in recurrent vertigo is almost always peripheral, the most common cause being benign positional vertigo. This condition is readily identified by a history of symptoms precipitated by head movement. Consciousness is preserved but the sensation of disorientation can be so profound that patients may report diminished awareness. Nausea and vomiting may also occur. Deafness, tinnitus and a history of ear infection will suggest Ménière's disease. Cerebellar stroke is the most common central cause of vertigo.

Hyperekplexia ('startle disease'). This refers to a rare group of disorders characterised by an exaggerated involuntary motor response to startle stimuli. Major and minor forms of the disorder have been distinguished (Bakker *et al.* 2006). The major form presents in the neonate with generalised stiffness that resolves in the first few years of life; an exaggerated startle response, especially to auditory stimuli, that persists throughout life; and a generalised stiffness that follows the startle response and lasts for a few seconds. The minor form of the disorder, which involves only an exaggerated startle response, is less common and less clearly delineated. In particular, minor forms of the disorder have not been as consistently linked to genetic abnormalities as have the major forms (Tijssen *et al.* 2002). Hyperekplexia usually has a genetic basis

Table 6.14 Paroxysmal neurological disorders that may be mistaken for epilepsy.

and over 70 pedigrees have now been reported. Most have mutations in the *GLRA1* gene encoding the α_1 subunit of the glycine receptor and show an autosomal dominant pattern of inheritance. The overwhelming majority of affected individuals have the major form of hyperekplexia but there are reports of the minor form of the disorder in some family members, with or without the mutation. Thus, family history is an important pointer to the diagnosis. The startle response is dramatic, may involve myoclonic movements and be associated with a fall but there is no alteration of consciousness. Non-familial hyperekplexia is rare and may have a sporadic genetic cause (Gaitatzis *et al.* 2004). Exaggerated startle is also seen in the stiff man syndrome and in association with brainstem or severe diffuse cerebral pathology. Hyperekplexia must be differentiated from *startle-induced epilepsy*. In the latter condition, epileptic seizures are triggered by sudden stimuli, most commonly auditory. Seizures typically arise in childhood and are often not exclusively related to startle, in which case startle-induced seizures may occur as a transient phase. Asymmetric tonic posturing is a common semiological feature of the seizures. Some patients have diffuse cerebral pathology and learning difficulties but around half are of normal intelligence without neurological signs. Dysplastic lesions in premotor and perisylvian cortices may account for many of the latter group (Manford *et al.* 1996b).

Paroxysmal movement disorders. Paroxysmal kinesogenic dyskinesia (or choreoathetosis) is the most common paroxysmal movement disorder (Vidailhet 2000). Patients develop sudden brief (usually less than 1 minute) attacks of dystonia or chorea triggered by voluntary movement (Bruno *et al.* 2004); 80% of patients report a brief 'aura' which may have an epigastric quality. Consciousness is not impaired. Exacerbation by stress and alcohol are common. Idiopathic cases, two-thirds of whom have a family history, begin before 20 years of age and may be associated with a history of non-febrile infantile convulsions. Treatment with low-dose antiepileptic medication is highly effective. Later-onset cases secondary to vascular, demyelinating and traumatic lesions have also been described (Blakeley & Jankovic 2002). Genetic linkage to chromosome 16 has been reported in a number of pedigrees. In paroxysmal non-kinesogenic dyskinesia, episodes are triggered by anxiety, caffeine and alcohol but not by movement. Episodes may be of longer duration (several minutes) and onset may be at any age, often in adulthood. Treatment with clonazepam is usually effective. Most cases are familial and the pattern of inheritance is typically autosomal dominant with incomplete penetrance. Mutations affecting the myofibrillogenesis 1 (*MRI*) gene on chromosome 2 have recently been reported, and appear to be associated with a phenotype characterised by early onset and precipitation by caffeine and alcohol (Bruno *et al.* 2007). A pedigree without these specific features was found to have

linkage to a site on chromosome 2 not involving the *MRI* locus (Spacey *et al.* 2006).

Episodes of spontaneous paresis with preserved consciousness lasting for hours are seen in periodic paralysis (Venance *et al.* 2006), which may present to seizure clinics. The primary periodic paralyses are autosomal dominant conditions caused by mutations in genes encoding three specific ion channels. Secondary hypokalaemic periodic paralysis may occur in thyrotoxicosis. The periodic ataxias are also dominantly inherited channelopathies that present with brief (seconds to minutes) episodes of ataxia, sometimes associated with myokymia.

Sleep disorders are quite commonly considered in the differential diagnosis of epilepsy (see Chapter 13). In narcolepsy, daytime episodes of somnolence typically occur in settings where attentional demands are reduced but they may seem precipitous, a good example being attacks during a telephone conversation. However, the episodes are usually clearly described as being preceded by an irresistible urge to sleep and are seldom mistaken for epilepsy. Afterwards, the patient wakes feeling refreshed. Emotionally triggered loss of muscle tone in cataplexy may be associated with a fall. Consciousness is not impaired and recovery almost immediate (rarely taking longer than 1 minute). Cataplexy seldom if ever occurs other than in association with narcolepsy, but it may be the presenting feature of the syndrome. The other features of narcolepsy (hypnagogic/hypnopompic hallucinations and sleep paralysis) are found in around one-third and one-quarter of patients, respectively. The distinction between epilepsy and sleep disorders associated with paroxysmal motor and behaviour disturbance may be more difficult (see Derry *et al.* 2006 for a comprehensive review). In particular, FLE, which may occur exclusively in sleep and is often characterised by bizarre semiological features, is easily mistaken for sleep disorder and vice versa. Non-REM arousal disorders (confusional arousals, somnambulism and sleep terrors) may be relatively stereotyped, and their duration (minutes) does not clearly differentiate them from epileptic automatisms. However, they tend to occur less frequently and are less likely to show clustering than epileptic seizures, especially frontal seizures. They occur during stage 3 and 4 sleep, typically 90 minutes to 2 hours after sleep onset, whereas epileptic seizures tend to occur in stage 2 sleep, usually within 30 minutes of sleep onset. *REM sleep behaviour disorder* involves complex, sometimes violent, behaviour in which dreams are enacted during a sleep automatism. After the event, patients will usually, but not invariably, remember the dream that led to their actions but have no recall of their behaviour. Older age at onset, associated degenerative neurological disease, a history of vivid dreams and rousability during the episode are useful distinguishing features. Overall, it is the lack of epileptiform features that distinguishes these parasomnias from epilepsy. However, a clear

eyewitness account of the episodes is often not available and video-EEG monitoring will often be required.

Transient global amnesia

Transient global amnesia (TGA) is a striking clinical syndrome. Patients present in an alert, perplexed, often agitated state, having abruptly become aware that they are unable to remember recent events. They are also unable to retain new information. Cognitive function is otherwise remarkably preserved. Episodes last for an average of 4 hours and resolve gradually. On recovery, the patient has no memory for the episode. In most cases the episode is an isolated one and TGA is regarded as a benign condition that requires no treatment. Aetiology is uncertain. Ischaemia, cerebral venous congestion, and migraine have all been put forward as possible mechanisms (Quinette *et al.* 2006). Patients with epilepsy are specifically excluded in diagnostic criteria for TGA. However, there may be some overlap with transient epileptic amnesia. Recent descriptions of transient epileptic amnesia emphasise that clinical evidence of epilepsy is often subtle and indeed may be absent in 30% of patients (see Transient epileptic amnesia, earlier in chapter). The pattern of amnesia in the two syndromes may overlap but retrograde amnesia is the conspicuous feature in transient epileptic amnesia and may extend back in time for years. Anterograde amnesia is also present in transient epileptic amnesia but patients may have some memory of the episode on recovery, unlike those with TGA in whom the main feature is a dense anterograde memory deficit.

Endocrine and metabolic disorders

Among endocrine and metabolic disorders with paroxysmal presentations, hypoglycaemia is the most common. Symptoms may include blurred vision, diaphoresis, and behavioural changes with delirium, anxiety and agitation. Hypoglycaemia occurs most commonly in the context of insulin therapy. Other causes include alcohol, renal or hepatic disease, insulin-producing tumours and hereditary fructose intolerance. Paroxysmal symptoms may also be seen with hypocalcaemia secondary to hypoparathyroidism, pheochromocytoma and carcinoid syndrome.

What is the aetiology?

If seizures are judged to be epileptic, it is important to determine whether they may have been provoked by some extrinsic or non-recurrent factor. Some 40% of incident seizures fall into this category (Annegers *et al.* 1995). In children, a febrile illness is the most common provoking factor. In adults, traumatic brain injury, cerebrovascular disease, alcohol withdrawal and CNS infection are the most common causes. A combination of sleep deprivation and alcohol are the most likely factors in a young adult. Where seizures seem to have occurred without obvious provoking factors, the history may point to a likely aetiology. Age at onset of seizures provides the most important clue. Epilepsy due to congenital

disorders and perinatal insults is likely to present in infancy. From early childhood through to adolescence, febrile convulsions, CNS infection and then the idiopathic generalised epilepsy syndromes predominate. Most cases of cryptogenic and symptomatic localisation-related epilepsy will have presented by early adulthood. With increasing age, trauma, malignancy and then cerebrovascular and degenerative disorders become the most likely causes. Specific enquiry should accordingly be made about perinatal history, developmental delay, febrile convulsions, head injury (with loss of consciousness), history of CNS infection and family history of epilepsy. It should be noted that patients with psychogenic non-epileptic seizures frequently report a history of neurological problems and a family history of seizures may be more common in this group than in people with epilepsy (Wilkus *et al.* 1984; Moore & Baker 1997). A recent history of progressive neurological symptoms, and systemic symptoms of malignancy, will suggest a primary or metastatic tumour. Physical examination is often not rewarding but may reveal dermatological stigmata of the neurocutaneous syndromes or signs of neurological or systemic illness.

Investigation

Electroencephalography

Most EEG recordings in patients with seizures are obtained interictally when the patient is asymptomatic. If the interictal EEG is abnormal, then it may provide support for a diagnosis of epilepsy. Conversely, if the interictal recording is normal, this may make a diagnosis of epilepsy less likely. However, the interictal EEG can never be relied on to exclude a diagnosis of epilepsy, or indeed to prove it. To appreciate the role an interictal EEG may have in 'supporting' a clinical diagnosis of epilepsy it is important to understand the specificity and sensitivity of EEG. How often is the EEG abnormal in healthy individuals? How often is it normal in people with epilepsy? What factors make a false-negative or false-positive result more likely, and how can these misleading results be avoided, or at least minimised?

There is a relative paucity of information about EEG findings in healthy individuals. The most frequently quoted evidence comes from studies of military aircrew candidates who are routinely screened with EEG. The largest of these involved over 13 000 young men with no significant past medical history and normal physical examinations (Gregory *et al.* 1993). Clearly defined epileptiform abnormalities (spikes, certain spike-and-wave discharges, and/or a spike-and-wave photoparoxysmal response) were present in 0.5%. Follow-up information on those individuals with abnormal EEG was limited in this and other studies but the results have been broadly similar, suggesting that the risk of developing epilepsy after such an EEG finding is approximately twice that in the normal population. Overall, these studies have therefore suggested that epileptiform abnormalities will be

found in about 0.3–0.5% of healthy adults who are at no discernible increased risk of epilepsy. By any standards such figures for specificity seem reasonably high. If an otherwise healthy person has a blackout and the EEG shows epileptiform abnormalities, it is highly likely that epilepsy is present. Why is it then that one authority in the field (Chadwick 1994) was moved to comment that ‘routine interictal EEG recording is one of the most abused investigations in clinical medicine and is unquestionably responsible for great human suffering’? The problem concerns two particular sources of false positives. The first involves ‘over-reporting’ and ‘over-interpretation’ of EEG findings: non-specific changes in the EEG, and certain normal variants, are all too easily misreported as epileptiform; or reported as ‘non-specific abnormalities’, which is then misinterpreted as suggesting epilepsy (Benbadis & Tatum 2003). The second problem relates to the fact that in clinical populations the prevalence of false-positive epileptiform findings may be much higher. The incidence of epileptiform abnormalities rises to 10–30% in patients with congenital or acquired CNS disorders such as head trauma, tumours and perinatal injury (Zivin & Ajmone Marsan 1968). Both sources of false-positive error are of particular relevance to patients with dissociative seizures. A proportion of such patients have learning difficulties and consequently demonstrate a higher incidence of epileptiform abnormalities than healthy controls. However, potentially more problematic is the finding that, even after excluding such patients, *non-specific* abnormalities are over-represented in patients with dissociative seizures (Reuber *et al.* 2002). The significance of this finding is uncertain, but it may relate to an association between personality disturbance and non-specific EEG findings that does not seem to be accounted for by overt neurological disorder (De la Fuente *et al.* 1998).

Approximately 50% of patients with epilepsy will demonstrate an epileptiform abnormality during their first routine EEG recording (Fowle & Binnie 2000; Smith 2005). Repeated recordings will increase the yield of significant findings, but around one-third of patients are likely never to show an abnormality during an EEG obtained in the alert state. A recording obtained during sleep (either spontaneous or drug induced) will increase the rate of positive findings to around 80%. Overall, interictal epileptiform discharges are most likely in patients with frequent seizures (Sundaram *et al.* 1990) and, in a patient with daily seizures, an entirely normal interictal EEG will raise strong suspicion of non-epileptic seizures. The sensitivity of interictal EEG is higher in children than in adults, and higher in TLE than in patients with mesial or basal (especially frontal) epileptogenic foci. Hyperventilation and photic stimulation should be included as part of routine EEG protocols. Hyperventilation will trigger a seizure in most children with juvenile absence epilepsy, which is associated with a characteristic 3-Hz discharge (thus affording a reliable and simple method of obtaining an ictal

EEG in this situation). A generalised spike-and-wave photoparoxysmal response to photic stimulation is strongly correlated with clinical generalised epilepsy. Photosensitivity is rare in localisation-related epilepsy.

An ictal EEG, especially when accompanied by video recording (video-EEG telemetry) of clinical semiology, is the gold standard for diagnosis. Telemetry should always be considered when there is doubt about diagnosis, the threshold for referral being determined primarily by practical considerations concerning availability and cost, as well as how frequently the person is having seizures. The diagnostic findings in epilepsy are an ictal discharge, clear evidence of postictal slowing and/or a preserved alpha rhythm in an unresponsive patient (Meierkord *et al.* 1991). Quite large areas of cortex (a few square centimetres) need to be involved in synchronous discharges before an abnormality is seen on the scalp EEG. Simple partial seizures and frontal seizures arising in medial or basal regions are therefore often not accompanied by any scalp EEG change. An ictal EEG may still be useful in distinguishing frontal lobe seizures from dissociative episodes when seizures occur during sleep: frontal lobe seizures will be seen to arise directly from electrographically documented sleep; in patients with dissociative seizures, the EEG will reveal a period of arousal from sleep (typically inconspicuous to an observer, so-called pseudosleep) that precedes seizure onset (Duncan *et al.* 2004). Movement artefacts may obscure the EEG and, if rhythmic, may even be mistaken for epileptic discharges. The evaluation of patients with multiple seizure types requires special diligence. Because dissociative seizures often coexist with epilepsy, care must be taken to ensure that each type of seizure has been documented before concluding that the patient has, or does not have, epilepsy. It is important to verify, with the patient and with informants, that the episodes captured are indeed examples of the patient’s habitual seizures. Occasionally, a patient is encountered who has a first, and last, dissociative seizure during an admission for telemetry. A further problem concerns patients who have epileptic partial seizures that trigger a dissociative non-epileptic elaboration (Kapur *et al.* 1995). Provocation techniques, for both epilepsy and non-epileptic seizures, may be used. In certain circumstances, withdrawal of antiepileptic drugs may be considered in evaluating seizures thought likely to be epileptic in order to increase the chances of capturing a seizure or possibly to unmask epileptic discharges that might be suppressed by medication. Between 50% and 90% of patients with dissociative seizures will have attacks induced by suggestion. Techniques involving placebo (e.g. intravenous saline, alcohol skin patches) are effective but raise significant ethical issues. More recently, McGonigal *et al.* (2002) were able to provoke dissociative seizures in two-thirds of patients using simple suggestion with routine photic and hyperventilation stimuli, fully disclosing the aims of the procedure to patients. These authors estimate

they were able to reduce the need for prolonged telemetry admission in 47% of patients. Provocation may be of particular value in patients who have infrequent seizures and would otherwise be unsuitable for telemetry. There is a small risk of false-positive results with these provocation techniques and it is therefore critical that an informant who has witnessed the patient's seizures is available to confirm that the provoked seizure resembles the habitual ones.

The EEG has a valuable role in determining seizure type and epilepsy syndrome (Fowle & Binnie 2000; Smith 2005). Two clinical situations are particularly important in this context. The first concerns the differentiation of complex partial and absence seizures, which may sometimes be difficult based on history alone. The second concerns partial seizures with rapid secondary generalisation, which may be mistaken for primary generalised epilepsy. In addition, a number of infantile and childhood syndromes are characterised by specific EEG appearances, for example West syndrome, benign childhood epilepsy syndromes and Landau-Kleffner syndrome. Other than helping establish seizure type and identifying the syndrome, the EEG has a limited role in guiding treatment decisions. An abnormal EEG following a first seizure may influence the decision to start treatment. The risk of seizure recurrence following a first unprovoked seizure rises from 27% when the EEG is normal to 58% when epileptiform abnormalities are present (Berg & Shinnar 1994). The decision to withdraw antiepileptic drugs after seizure remission is discussed in Management of epilepsy in remission, later in chapter. A normal EEG is one factor that may be taken into account but it has a relatively low predictive value.

The EEG plays an important role in the diagnosis of non-convulsive status epilepticus and in the management of status epilepticus in intensive care settings. In the latter situation, EEG is essential for monitoring treatment response when anaesthesia and paralysing agents may conceal overt seizure activity. Along with MRI, the EEG has a central role in the assessment of patients for surgery (see Surgical treatment of epilepsy, later in chapter).

Neuroimaging

Magnetic resonance imaging is the structural imaging method of choice in epilepsy (see Duncan 1997b; Connor & Jarosz 2001). CT has a much lower sensitivity but will be used when MRI is contraindicated or in acute settings where CT allows better access to a medically unstable patient during scanning. In addition, CT has advantages over MRI in the detection of acute intracranial haemorrhage and skull fracture and is a useful supplement to MRI in the identification of small areas of intracranial calcification. The Commission on Neuroimaging of the International League Against Epilepsy (1997) have recommended that MRI be obtained in all patients with epilepsy, with the exception of those with a definite diagnosis of idiopathic generalised epilepsy or benign rolandic epilepsy of childhood. MRI is particularly indicated

in the following situations: (i) onset of partial seizures at any age; (ii) onset of unclassified or generalised seizures in the first years of life or adulthood; (iii) where there is evidence of a focal neurological or neuropsychological deficit; (iv) when seizures are poorly controlled with first-line treatment; and (v) where there is loss of seizure control or a changing pattern of seizures. Where access to MRI is restricted, priority should be given to patients whose seizures are not controlled with medical treatment or who have progressive neurological or neuropsychological deficits.

Magnetic resonance imaging will detect a lesion in over 80% of patients with chronic epilepsy. Hippocampal sclerosis is the most commonly identified pathology. Other abnormalities include disorders of neuronal migration and cortical development, tumours, vascular malformations and acquired cortical injury. A typical MRI protocol should include oblique coronal images obtained orthogonal to the long axis of the hippocampal structures. T1- and T2-weighted datasets should be obtained. The main findings in hippocampal sclerosis are hippocampal atrophy and increased T2-weighted signal within the hippocampus. Visual inspection will detect a 20% or greater degree of hippocampal asymmetry. Quantitative methods for assessing both hippocampal volume and T2 signal abnormality have been described. The resource implications of these methods have meant that their clinical use has been restricted to the presurgical evaluation of patients with equivocal findings on qualitative review of scans. Hippocampal atrophy may be bilateral in up to 15% of cases (Margerison & Corsellis 1966; King *et al.* 1995) and not uncommonly occurs in association with other pathologies. Careful inspection for hippocampal sclerosis is therefore essential even if other pathology is identified, and vice versa. Subtle abnormalities of cortical development are found in up to 7% of patients with chronic partial epilepsy and are likely to account for a substantial proportion of those who are currently 'MRI-negative'. Advances in MRI hardware, including higher magnetic field strength (3 T), will improve anatomical resolution and may further improve the sensitivity of structural MRI in epilepsy.

Functional imaging has a growing role in the presurgical evaluation of localisation-related epilepsy (see Duncan 1997b, 2003; Richardson 2001). Images of cerebral blood flow obtained with SPECT demonstrate focal interictal hypoperfusion and ictal hyperperfusion. The interictal findings have a relatively poor correlation with seizure localisation but ictal hyperperfusion on SPECT is a more reliable marker of seizure onset and has an established place in presurgical assessment in some centres. PET may similarly be used to demonstrate regional metabolic changes in association with seizures. However, PET ligand studies of the distribution of benzodiazepine, opioid and other receptors seem to offer greater potential for seizure localisation. For example, benzodiazepine receptor studies with the ligand ^{11}C -flumazenil demonstrate focal reductions in receptor density that correlate well with MRI findings in hippocampal sclerosis and in

malformations of cortical development. In the latter situation, ligand studies may prove helpful in locating seizure foci in MRI-negative patients. Functional MRI is being developed to delineate motor and speech cortex as part of surgical planning. Techniques linking EEG, functional MRI and structural MRI have the potential for allowing anatomical mapping of the source of interictal epileptiform discharges.

Cardiological investigations

Most cases of vasovagal syncope are readily identified on history alone and do not require further investigation. In uncertain cases, when episodes are frequent, or where underlying cardiac disorder is suggested by history or examination, cardiological assessment is required. The important alarm signals in the history are a personal or family history of heart disease, a lack of presyncopal symptoms, and a history of syncope occurring with exercise, when lying or in association with palpitations or chest pain (Brignole 2007). A routine ECG, echocardiography and a 24-hour ECG recording are usually the first steps. These are relatively inexpensive and will identify structural cardiac disease but will miss some causes of paroxysmal arrhythmias. Tilt table testing will help confirm a syncopal tendency, and will identify most cases of orthostatic syncope and many cases of vasovagal syncope. However, the sensitivity (50%) is relatively low and false-positive results are seen in up to 15% of normal individuals (Gould *et al.* 2006). Sensitivity may be increased with various pharmacological provoking agents but at the expense of lower specificity. In the elderly, carotid-sinus massage with ECG monitoring may be used to investigate carotid sinus hypersensitivity. This procedure also has poor specificity, with around one-third of asymptomatic individuals over the age of 65 demonstrating a false-positive result (Kerr *et al.* 2006). If a strong suspicion of vasovagal syncope or arrhythmia remains despite normal preliminary investigations, longer-term ECG monitoring should be considered. This can be performed using either an external or an implanted 'loop' ECG monitor. An implanted device is invasive and relatively expensive but provides high-quality recordings for up to 18 months and does not suffer from the problems of compliance encountered with external devices. Loop monitors record the ECG continuously. After an episode the patient triggers an event-switch on the device, which then stores the preceding epoch of ECG for later analysis. The device can also be programmed to save recordings automatically in association with episodes of bradycardia or tachycardia. Internal loop recorders will lead to an ECG-based diagnosis and treatment in around one-third of patients and appear to be cost-effective (Brignole *et al.* 2006; Farwell *et al.* 2006). There is growing evidence that dual-chamber cardiac pacemakers are an effective treatment for recurrent vasovagal syncope (Morgan 2006).

The occurrence of sinus bradycardia and syncope during epileptic seizures has been mentioned in the preceding

section on clinical evaluation. However, the real importance of ictal bradycardia lies in its relationship to ictal asystole which, along with ictal apnoea, is likely to be an important mechanism in sudden seizure-related deaths (Nashef *et al.* 2007). The wider implications of ictal bradycardia in terms of management, including indications for cardiological investigations and monitoring, have not yet been established. However, in one highly selected series of 19 patients with intractable localisation-related epilepsy, monitoring with implanted ECG loop recorders over 18 months revealed ictal bradyarrhythmias in seven patients, four of whom subsequently received permanent pacemaker insertion (Rugg-Gunn *et al.* 2004). An important finding was that serious arrhythmias occurred only intermittently in the affected patients; between episodes of ictal bradycardia there were typically many seizures without any significant cardiac effects. Thus, an isolated normal ictal ECG recording, obtained for example during presurgical work-up, provides little or no reassurance that the patient is not at risk.

Serum prolactin

Serum prolactin rises after tonic-clonic epileptic seizures, peaking 10–20 minutes after the seizure and returning to baseline after about 6 hours (Chen *et al.* 2005). A rise in prolactin is less reliable following complex partial seizures, may be absent following serial epileptic seizures or in status epilepticus, and is not seen following simple partial seizures. Syncope may also be associated with elevated prolactin levels and, potentially more problematically, modest rises in prolactin have been described in patients with psychogenic non-epileptic seizures (Alving 1998; Willert *et al.* 2004). As a result, and because video-EEG monitoring is now more widely available, the test has fallen out of favour. However, a negative finding after an apparent tonic-clonic seizure is still helpful. Blood samples should be taken 10–20 minutes after a seizure and compared with a baseline sample taken at approximately the same time of day and at least 6 hours after a seizure. Criteria for a positive result have varied between studies but a twofold rise above baseline is widely regarded as significant. The American Academy of Neurology (Chen *et al.* 2005) have concluded that the postictal prolactin test is a useful adjunct for differentiating generalised and complex partial seizures from psychogenic events and recommended further studies to establish the sensitivity and specificity of the procedure.

Treatment

The aim of treatment is to achieve seizure control with a minimum of adverse effects. Complete remission is a realistic target for most patients who can then expect a quality of life comparable to that of the general population. When this is not possible, a secondary aim is reduction in seizure

frequency or severity. However, this is very much a 'second best' outcome. Continuing seizures, no matter how infrequent, have a significant impact on overall quality of life, social functioning and psychiatric status (Leidy *et al.* 1999; Birbeck *et al.* 2002; Gilliam 2002). In addition, epilepsy is associated with significant mortality and a risk of accidental injury. Patients whose seizures are not fully controlled therefore constitute a special clinical group requiring careful reappraisal and a clearly defined, active management plan. Seizure freedom should not, of course, be pursued at any cost. Treatment will always represent a compromise between reducing seizure frequency or severity and keeping side effects to an acceptable minimum. Shorvon (2004) has commented that 'there is often a strange inertia in much of the treatment of chronic epilepsy'. The phrase 'well-controlled epilepsy with infrequent seizures' should always strike a note of alarm. Epilepsy that is not in remission is poorly controlled.

The higher mortality rate and risk of injury associated with epilepsy are important factors underlying the rationale for treatment. Overall, patients with epilepsy have a standardised mortality ratio of 2–3 (O'Donoghue & Sander 1997). Causes of this excess mortality include death due to the underlying cause of epilepsy, accidental injury, suicide, status epilepticus and sudden unexplained death. The risk of sudden unexplained death in epilepsy (SUDEP; see Sudden death in epilepsy) is probably small in most cases of recent-onset epilepsy but may be as high as 1 in 100 patients per year in those with medically intractable epilepsy awaiting surgery (Dasheiff 1991). Most accidental injuries in people with epilepsy are seizure related (Wirrell 2006). Children and patients with generalised tonic-clonic seizures are at greatest risk. Retrospective studies have suggested a threefold to sixfold increased risk of submersion injury, with incidents during bathing being more common than those related to swimming. Burns, fractures and head injuries are also more common. However, the overall incidence of these problems is relatively low. There has been only one prospective controlled study of accidental injury in epilepsy (Beghi & Cornaggia 2002). Over 12 months, accidental injuries occurred in 17% of 952 people with epilepsy and 12% of 909 controls. After 2 years the corresponding figures were 27% and 17%. Most injuries were minor but patients with epilepsy reported a higher rate of injuries requiring hospitalisation (3% vs 1%) or medical treatment (16% vs 10%). At each stage in treatment, these risks, together with the psychosocial burden of ongoing seizures, must be weighed against the likelihood that a proposed treatment will be successful and without significant side effects. As previously mentioned, the risks of untreated epilepsy in the early stages are probably insignificant compared with the dire consequences of a mistaken diagnosis of epilepsy. Treatment should only be instituted when diagnosis is certain.

When to start treatment

Treatment is indicated if a patient has had two or more unprovoked seizures occurring within a relatively short interval. Most would consider recurrence within 6 months or 1 year as falling into this category. In practice, seizures usually occur at shorter intervals and the decision to begin treatment is straightforward. This is especially so when a syndromic diagnosis, for example JME, has been made. A more difficult, but not uncommon, problem arises when a patient presents following a single, apparently unprovoked, tonic-clonic seizure. In this situation further investigations will help inform treatment decisions. Overall, the risk of recurrence over a 2-year period following a single unprovoked seizure is approximately 30–40%. The lowest risk (24%) is in patients with no identifiable cause and a normal EEG. Where a cause is found and the EEG is abnormal, the chance of a second seizure is as high as 65% (Berg & Shinnar 1991).

Some patients with mild forms of epilepsy may decide not to pursue treatment. The question of whether delaying treatment has an adverse effect on long-term prognosis then arises: do seizures beget seizures? Elwes *et al.* (1988) studied patients presenting with untreated tonic-clonic seizures and found the median interval between seizures showed a progressive decline, from 12 weeks between the first and second seizures to 3 weeks between the fourth and fifth. This seemed compatible with an accelerating underlying disease process. Other evidence, however, suggests that epilepsy is generally a non-progressive disorder and there is little if any harm in delaying treatment. For example, studies of untreated epilepsy have found that it may run a relatively benign course with spontaneous seizure-free periods of a year or more occurring in nearly 50% of patients (Placencia *et al.* 1994). There is also evidence that treatment begun many years after the onset of epilepsy achieves similar results to that initiated soon after seizure onset (Fekski *et al.* 1991).

Prophylactic treatment after brain injury or supratentorial neurosurgery should be avoided. Such treatment may decrease the incidence of acute symptomatic seizures in the first week, but confers no protection against seizures in the longer term (Schierhout & Roberts 1998). The needless prescription of antiepileptic drugs undoubtedly contributes to the cognitive and behavioural difficulties in many such patients. One of the most rewarding medical interventions in a neurorehabilitation setting is the withdrawal of unnecessary antiepileptic drugs, an action that is often followed by remarkable improvements in alertness, communication and overall neurological function.

Choice of treatment

The choice of initial drug treatment is dictated by type of seizure and syndrome, patient characteristics, side effects and practical considerations such as availability and cost.

Seizure type/syndrome

Carbamazepine has long been regarded as the drug of first choice for localisation-related epilepsy. Most recently, this view has been challenged by the results of a large multicentre trial in the UK, the Standard and New Antiepileptic Drugs (SANAD) trial (Marson *et al.* 2007a); 1721 patients for whom carbamazepine was deemed the standard treatment were randomly allocated to receive carbamazepine, lamotrigine, oxcarbazepine, gabapentin or topiramate. In terms of efficacy, carbamazepine showed an advantage in relation to time to 12-months seizure remission, but this was statistically significant only in comparison with gabapentin. However, time to treatment failure (failure to control seizures or the advent of intolerable side effects) was longer for lamotrigine, and this difference was statistically significant in relation to all drugs except oxcarbazepine. The authors concluded that lamotrigine was a cost-effective and well-tolerated alternative to carbamazepine.

Valproate remains the drug of choice for generalised epilepsy (Marson *et al.* 2007b). As valproate is associated with adverse cosmetic and teratogenic effects (see below), young women with generalised epilepsy present a particularly difficult treatment dilemma. Ethosuxamide is an alternative treatment for absence seizures but is ineffective for generalised tonic-clonic seizures.

The spectrum of efficacy of antiepileptic drugs is listed in Table 6.15. The table is based on recent reviews (McCorry *et al.* 2004; Perucca 2005) and guidelines published by the American Academy of Neurology (French *et al.* 2004a,b) and the ILAE (Glauser *et al.* 2006). Felbamate and vigabatrin have been omitted from the table as their use is now restricted because of toxicity. Efficacy has been established for a number of the newer drugs as add-on treatment only.

Drug toxicity

Antiepileptic drugs are associated with four categories of adverse effects (Smith & Chadwick 2001): (i) acute dose-related toxicity; (ii) acute idiosyncratic reactions; (iii) chronic toxicity; and (iv) teratogenicity.

Acute dose-related toxicity is common. The most frequent symptoms are referable to the CNS and include drowsiness, cognitive disturbance, headache, ataxia and visual disturbance. Nausea and other gastric symptoms are also common. These symptoms are usually mild and transient. They improve as tolerance to the drug develops, usually within a week or two at any given dose, and can be relieved by lowering the dose and subsequently slowing the rate of dose titration. Nevertheless, these side effects are a common reason for treatment failure.

Acute idiosyncratic reactions are rare but potentially life-threatening and require immediate drug withdrawal. Allergic reactions with a rash occur in 2–4% of patients taking carbamazepine, phenytoin, phenobarbital and, perhaps more commonly, lamotrigine. These reactions typically occur in the first 4 weeks of treatment and may be accompanied by symptoms of systemic illness. The same drugs are also associated with Stevens–Johnson syndrome and Lyell’s syndrome, rare but potentially fatal cutaneous reactions. Severe haematological complications are reported with felbamate, acetazolamide, carbamazepine, phenytoin, lamotrigine and zonisamide. Such reactions are rare with the exception of felbamate, use of which is now restricted because of its association with aplastic anaemia and liver toxicity. Acute hepatotoxicity is a rare complication of valproate and occurs almost exclusively in children with complex

Table 6.15 Effectiveness of antiepileptic drugs against different seizure types.

	Partial-onset seizures	Generalised onset: tonic-clonic seizures	Generalised onset: absence seizures
<i>First line</i>	Carbamazepine Lamotrigine	Valproate	Ethosuxamide
<i>Alternatives</i>			
First generation	Valproate Phenobarbital Phenytoin Benzodiazepines	Carbamazepine* Phenobarbital Phenytoin* Benzodiazepines	Valproate
Second generation	Gabapentin Levetiracetam Oxcarbazepine Tiagabine Topiramate Zonisamide Pregabalin	Lamotrigine Topiramate Levetiracetam?	Lamotrigine

* May exacerbate myoclonic and absence seizures.

neurological disorders on polytherapy. Acute liver failure is also rarely reported with phenytoin and carbamazepine.

Chronic toxicity. These effects are usually not directly life-threatening but may be irreversible. Important examples include cosmetic effects with phenytoin (hirsutism, coarsening of facial appearance, gum hyperplasia) and valproate (weight gain, alopecia and tremor), hyponatraemia with carbamazepine and oxcarbazepine, folate deficiency with phenytoin, phenobarbital, valproate and carbamazepine, weight loss and renal calculi with topiramate, visual field defects with vigabatrin (which severely restrict its use), and endocrine and bone effects with many drugs, particularly those that induce hepatic enzymes (phenytoin, carbamazepine and phenobarbital).

Teratogenicity. The risk of major congenital malformations in children born to women taking antiepileptic drugs is about 5–9%, approximately twice the rate observed in the general population (Samren *et al.* 1997; Kaneko *et al.* 1999; Holmes *et al.* 2001). The most commonly reported malformations include neural tube defects, cardiac malformations and skeletal abnormalities. Minor anomalies, including certain dysmorphic facial characteristics, have also been described but their prevalence is less certain. Patients taking more than one antiepileptic drug are at greatest risk and there is evidence that the risk is related to higher doses for some drugs. Overall, the risk of major malformations is highest with valproate, especially at doses above 1000 mg daily, but phenytoin, phenobarbital, lamotrigine and carbamazepine are all implicated. However, more recently introduced drugs must not be regarded as safe. They have not been in use long enough to allow even preliminary judgements to be made. Registers of pregnancies in women with epilepsy have been established in a number of centres and are the subject of ongoing investigation. Morrow *et al.* (2006) have reported outcome in 3607 pregnancies from the UK register, the largest study so far. The analysis focused on outcome for women taking carbamazepine (900 women), valproate (715) or lamotrigine (647), as well as a small group (239) of women with epilepsy who had not taken medication during pregnancy. Overall, major congenital malformations were seen in 4.2% of births to women who had taken antiepileptic drugs during pregnancy, and in 3.5% of those who were not taking medication. The risk of malformations was 6% in women on polytherapy compared with 3.7% in those taking a single drug. The rate of malformations was greater in those exposed to valproate (6.2%) than to lamotrigine (3.2%) or carbamazepine (2.2%), but the difference was statistically significant only for the comparison between valproate and carbamazepine. The highest risk (9%) was seen in patients receiving polytherapy combinations that included valproate. Interestingly, a significant relationship between dose and risk was observed for lamotrigine, but was discernible as a trend only for valproate. These results confirm previous impressions that valproate is

associated with the highest risk of major congenital malformations but also suggest that lamotrigine is not as safe as had previously been hoped. Finally, there is emerging evidence that children exposed to antiepileptic drugs *in utero* are at increased risk of developmental delay, learning and behavioural difficulties, and possibly autistic spectrum disorder (Eriksson *et al.* 2005; Rasalam *et al.* 2005; Vinten *et al.* 2005). Valproate has again been implicated in most of these studies but further prospective investigations are required.

Drug interactions are an important further complication in the treatment of epilepsy (Perucca 2006). This is mainly because antiepileptic drugs are often prescribed on a long-term basis and also because polytherapy is, unfortunately, quite common. An important category of interactions concerns drugs that induce the cytochrome P450 enzymes, the main examples being carbamazepine, phenytoin and barbiturates. Through this mechanism these drugs effectively shorten the half-lives of many other compounds, resulting in reduced serum levels and increased dosage requirements. This may affect other antiepileptic medication, oral contraceptives, anticoagulant treatment, analgesics, psychotropics and many other drugs. Enzyme inhibition may also occur, the most noteworthy example being the inhibition of lamotrigine metabolism by valproate, an action which effectively halves the dose requirements of lamotrigine. This is particularly important when prescribing lamotrigine for a patient already taking valproate, as the incidence of hypersensitivity reactions to lamotrigine seems to be related to the rate at which its serum levels rise. Accordingly, the starting dose of lamotrigine should be halved in this situation and dose increments made more slowly. In relation to psychotropics, interactions are seldom clinically significant (Spina & Perucca 2002). Reduced concentrations of tricyclic antidepressants, conventional neuroleptics (haloperidol, chlorpromazine) and atypical neuroleptics (clozapine, olanzapine, risperidone) have been reported in association with enzyme-inducing drugs. Fluoxetine and sertraline may increase serum levels of phenytoin and carbamazepine, and sertraline may cause a rise in lamotrigine levels.

Patient characteristics

Choosing the right drug for the right patient involves consideration of potential side effects in the context of patient characteristics. Age, gender and comorbidity are the most important factors in this context (Crawford *et al.* 1999; McCorry *et al.* 2004; Brodie & Kwan, 2005). Age influences the likelihood, as well as the impact, of certain adverse reactions and is often an important consideration in drug choice. For example, the hepatotoxicity associated with valproate is seldom seen in children older than 2 years. Skin reactions with lamotrigine are also more likely in children. Sedation, cognitive difficulties and behavioural problems may be associated with many of the antiepileptic treatments in children and can have a grave impact on educational achievement

and social functioning. The cosmetic effects of phenytoin and valproate may be of little concern to an older man but are highly significant considerations in children and young women. Acute dose-related CNS side effects, in particular sedation, are more likely in the elderly and in patient groups with static or progressive neurological disorders affecting cognitive functioning. Whereas in younger patients these effects are usually transient, this is often not the case in the elderly or in patients with diminished cerebral reserve. In more severely impaired patients with communication difficulties, sedation may not be conspicuous and subtle behavioural changes may be the only sign of toxicity. Lamotrigine and some of the newer antiepileptic drugs with favourable cognitive profiles may be more appropriate first-line choices in these patient groups. Decreased bone mineralisation is associated particularly with enzyme-inducing drugs, presumably through effects on vitamin D metabolism, but valproate has also been implicated. Older patients and postmenopausal women are particularly at risk. Bone density scans and calcium and vitamin D supplementation need to be considered. Finally, a number of special considerations apply to women of childbearing age. In view of the high rate of unplanned pregnancies, all fertile women should be considered 'at risk', not just those who are planning pregnancy. Information must be provided about contraception, including interactions between enzyme-inducing drugs and oral contraceptive preparations, and pregnancy. Folic acid should be prescribed as a matter of routine and oral vitamin K should probably be given in the last month of pregnancy. The choice of treatment in young women with idiopathic generalised epilepsy represents a particularly difficult dilemma for which there are no straightforward solutions at present (Duncan 2007). Lamotrigine has been favoured by many in this situation but the recent demonstration of significant teratogenic risk with lamotrigine now makes the choice more difficult. The main priority must be to provide women with clear information to allow them to weigh up the various alternatives.

Individual antiepileptic drugs

The following section is intended as a guide to the principal indications and important advantages or disadvantages of the most commonly prescribed antiepileptic drugs for adults. Prescribing guidelines are provided by the *British National Formulary* (2006). A comprehensive account is given in the standard text *The Treatment of Epilepsy* (Shorvon *et al.* 2004), which includes chapters devoted to each of the drugs currently in use.

Carbamazepine

Carbamazepine is a first-line drug for partial and tonic-clonic seizures. It is ineffective for, and may exacerbate, absence and myoclonic seizures. It has well-established efficacy and is usually well tolerated: acute dose-related CNS side effects (drowsiness, dizziness, mental slowing, ataxia,

diplopia, blurred vision) are transient and can usually be avoided with a low starting dose and slow increases. Hypersensitivity reactions include rashes, seen in 10%. Severe life-threatening haematological reactions (thrombocytopenia, aplastic anaemia, agranulocytosis and pancytopenia) have an estimated incidence of around 1 in 200 000. A mild subclinical leucopenia of under 5000 cells/mm³ is seen in around one-third of patients in the first 6 months. It may exacerbate atrioventricular conduction abnormalities and is therefore contraindicated in this situation. Carbamazepine is a hepatic enzyme inducer and has many drug interactions as a consequence.

Sodium valproate

Valproate has a wide spectrum of action. It is a drug of first choice in idiopathic generalised epilepsy and a first-line treatment for generalised seizures (of all types) and partial seizures. Acute dose-related CNS effects are mild and of a similar degree to those seen with carbamazepine. The most characteristic side effect is a dose-dependent intention tremor. Weight gain and alopecia (usually reversible on drug withdrawal) are relatively common and not infrequently lead to treatment withdrawal, especially in women. An association with polycystic ovary syndrome, presenting as menstrual disorder, obesity and hirsutism, is recognised although the incidence is uncertain. Fatal hepatotoxicity has been reported, almost exclusively in children less than 2 years old taking polytherapy in the context of complex neurological disorders. An encephalopathy associated with elevated ammonia levels has also been reported. The cosmetic, cognitive and teratogenic (see Drug toxicity, earlier) effects of valproate complicate its use in women. Valproate has a number of complex interactions with other antiepileptic drugs. The most significant relates to the addition of valproate to lamotrigine treatment, which may more than double serum concentration of the latter.

Ethosuximide

Ethosuximide is a first-line treatment for absence seizures for which it is probably equally effective as valproate. Ethosuximide is considered the drug of first choice for absence seizures in younger children (e.g. with onset before age 10) because it lacks the risk of liver toxicity associated with valproate and because generalised tonic-clonic and myoclonic seizures, for which ethosuximide is not effective, are less likely in this age group. Common side effects include gastrointestinal symptoms and non-specific CNS effects. More rarely, behavioural disturbance and psychosis have been reported.

Phenytoin

Phenytoin has a broad spectrum of action and may be considered as a first-line treatment for generalised and partial seizures. Non-linear pharmacokinetics mean that small adjustments in dosage may be accompanied by marked

changes in serum levels. A therapeutic range of serum concentration is reasonably well established, although clinical experience suggests that levels at the lower end of the range may be effective for generalised seizures whereas the higher end of the range may be required in patients with partial seizures. However, clinical response and side effects, rather than serum levels, guide dose selection in individual patients. The CNS dose-related effects are often quite severe and may be less transient than with other first-line drugs. Skin hypersensitivity reactions are seen in 5–10%. There are many systemic longer-term effects. Cosmetic side effects are important and include coarsened facial features, hirsutism and gum hyperplasia. Other longer-term effects include folate and vitamin K deficiency, osteomalacia, dyskinesias and, more rarely, peripheral neuropathy and cerebellar atrophy. Phenytoin induces hepatic enzymes with consequent drug interactions. While phenytoin is effective and broad spectrum, its acute and longer term side-effect profile place it behind other first-line treatments.

Barbituates

Phenobarbital is a cheap, highly effective, broad-spectrum treatment for generalised and partial seizures. Its use has declined because of a relatively high rate of neurotoxic effects, particularly sedation, cognitive slowing, and mood and behavioural disturbance (especially in children). Other relatively common side effects include folate and vitamin K deficiency, osteomalacia and soft-tissue abnormalities. It is a potent hepatic enzyme inducer. A further disadvantage is the occurrence of dependence and a withdrawal syndrome (which may include withdrawal seizures) when the drug is discontinued. Consequently, the rate of withdrawal must be extremely slow, over many months. *Primidone* is rapidly converted to phenobarbital but may also have an independent antiepileptic action.

Benzodiazepines

Clonazepam has a broad spectrum of action and is used as adjunctive treatment for partial and generalised seizures. Its use is limited primarily by its sedative effect, which may be severe, prolonged and associated with behavioural disturbance. Tolerance is also an important disadvantage and may be associated with both a loss of efficacy in some patients and a withdrawal syndrome on discontinuation. *Clobazam* also has a broad spectrum of action but is generally better tolerated than clonazepam. It may be a very effective adjunctive treatment but tolerance leads to reduced efficacy in up to 50% of patients. It is nevertheless a very useful treatment for some patients. *Clobazam* also has a special place as an intermittent treatment given for seizure clusters, as prophylaxis to cover special occasions and for catamenial seizures.

Lamotrigine

Lamotrigine is a first-line drug for partial and generalised seizures and is useful as both monotherapy and adjunctive

treatment. It is well tolerated, with less marked CNS effects than some of the older agents. The most important hypersensitivity reaction is a rash, which is seen in some 10%. The rash is typically maculopapular or erythematous, associated with pruritis, and appears some 4 weeks after starting treatment. Patients must be warned about this and treatment withdrawn if a rash appears: withdrawal should be carried out over about 2 weeks, more abruptly if skin reactions are severe. While a rash is seen as a hypersensitivity reaction with other antiepileptic drugs, its importance with lamotrigine relates to an association with rare but potentially life-threatening dermatological reactions including Stevens–Johnson syndrome and toxic epidermal necrolysis, which may be relatively more common with lamotrigine than other antiepileptic drugs. These severe reactions are more often seen in children and with rapid dose escalation. Special care must therefore be taken when adding lamotrigine to a patient already taking valproate. Lamotrigine levels may be lowered by enzyme inducers but the most important interaction is with valproate, which increases lamotrigine levels.

Gabapentin

Gabapentin is a second-line agent for adjunctive treatment of partial onset seizures and secondarily generalised seizures. It is well tolerated with relatively few CNS side effects and few, if any, significant drug interactions. Its efficacy in relation to other treatments remains uncertain but its favourable side-effect profile is a strong advantage.

Topiramate

Topiramate is a second-line agent, either as adjunctive treatment or as monotherapy, for partial seizures, with or without secondary generalisation, and for generalised tonic–clonic seizures. It is associated with marked dose-related CNS side effects, which can usually be minimised by introducing the drug very slowly. Cognitive effects, including problems with attention, memory and word finding, may be present with relatively little in the way of sedation. Weight loss is also common. Renal calculi occur in up to 2%. There have been recent reports of acute myopia and closed-angle glaucoma occurring in the first month of treatment. The drug should be withdrawn as rapidly as possible if this happens.

Levetiracetam

Levetiracetam is a recently introduced treatment (adjunctive or as monotherapy) for partial seizures, with or without secondary generalisation. It is also effective adjunctive therapy for myoclonic seizures. It is generally well tolerated. Sedation and other acute CNS side effects are relatively uncommon. Insomnia, dysthymia and other psychiatric and behavioural problems have been reported. There is preliminary evidence of efficacy with doses lower than currently recommended and also of seizure exacerbation at doses in the upper end of the currently recommended range.

Vigabatrin

Approximately one-third of patients treated with vigabatrin will develop a visual field defect that is almost certainly permanent. Its use is therefore now restricted to very special circumstances in severely disabling epilepsy where all other treatment combinations have failed, e.g. West syndrome.

Recently introduced antiepileptic drugs

Oxcarbazepine, tiagabine, pregabalin and zonisamide have been introduced too recently for any clear impression to have been formed of their value and side-effect profile. They are all considered second-line choices for adjunctive treatment of partial seizures, with or without secondary generalisation. Oxcarbazepine is an analogue of carbamazepine. It appears to be better tolerated than carbamazepine, although hyponatraemia may be more common. Other reported side effects include weight gain, alopecia and gastrointestinal disturbances. Preliminary experience with tiagabine suggests that CNS side effects, including cognitive difficulties, are relatively common and a cautious approach to dosing therefore seems important.

Treatment in practice

Treatment should begin with a single drug. The starting dose should be low and increases made slowly. In most cases there is no hurry to achieve a therapeutic dose and clinicians should not hesitate to err on the cautious (slow) side of prescribing guidelines (British National Formulary 2006). There are a number of important reasons for adopting the 'start low, go slow' approach. The main aim is to avoid acute dose-related adverse effects, the most common of which is sedation. Some idiosyncratic side effects are also more likely with excessively rapid dose escalation. However, the real cost of intolerable side effects at this stage is that they may result in a potentially useful treatment being abandoned prematurely, and the first drug will often have been chosen because it has very clear advantages over the alternatives. A further important reason for slow dose increases is that many patients will achieve seizure remission at doses well below the published therapeutic range.

Patients must be informed of the most common side effects and warned to seek advice immediately should they develop symptoms of an allergic reaction (e.g. rash, flu-like symptoms). The effectiveness of treatment is, of course, judged by seizure reduction and, ultimately, cessation. This will be recognised promptly in patients who have very frequent seizures but assessing efficacy may be a more protracted affair in those whose seizures occur infrequently. Unless seizures remit quickly it is extremely helpful for patients to record seizure frequency with a diary. If there are multiple seizure types, a simple code to identify each type of seizure is useful. If seizures do not stop, the dose is gradually increased until the patient experiences dose-related side effects. Ongoing

seizures when this point is reached mean that first-line treatment has failed.

When first-line treatment fails and a second drug is chosen the aim must still be monotherapy. Whether the first drug is reduced before starting the second, or the second drug added to the first (more common), will depend on seizure frequency and the presence of side effects. One of the most important principles in the medical treatment of epilepsy is that side effects, particularly dose-related toxic effects, are far more likely with polytherapy. Thus, the chance of achieving an effective dose of the second drug without side effects is greatly improved by withdrawing the first. This often means reducing the first drug as the second is increased, ideally before side effects are encountered. If remission is achieved and the patient has remained on both drugs, it is important to withdraw the first. Unfortunately, this is often forgotten and many patients are left unnecessarily on two drugs at this stage.

Serum levels of antiepileptic drugs are useful in very limited circumstances. A 'therapeutic range' is best established for phenytoin, but even this provides a rough guide only. If a patient is seizure-free and serum levels are below the lower end of the range, there is obviously no point in increasing the dose. Equally, some patients are able to tolerate levels above the therapeutic range, without toxic effects, and may benefit. The main use of serum levels is to assess compliance. Levels obtained before and after adding a second drug can also help assess the impact of any pharmacokinetic interactions and may guide dose adjustment. In patients on polytherapy who have non-specific toxic side effects, serum levels may help identify the culprit. Antiepileptic drugs may be associated with a variety of minor haematological and biochemical disturbances. Common examples include raised transaminases caused by enzyme induction, neutropenia and hyponatraemia with carbamazepine, and thrombocytopenia with valproate. However, these are seldom of any clinical significance and routine haematological and biochemistry screening is not required. Sensible times for blood tests are at baseline and prior to commencing additional drugs. In this way, if clinically significant problems do arise, the likely agent can more easily be identified.

Management after failed monotherapy

Around 60% of patients with symptomatic or cryptogenic epilepsy will become seizure-free with monotherapy (Mattson *et al.* 1996; Sillanpaa *et al.* 1998; Kwan & Brody 2000). For idiopathic epilepsy, the figure is closer to 70%. Once initial treatment has failed, however, the chances of achieving seizure remission with medical treatment alone fall below 10%. Failed monotherapy is therefore an ominous development and requires a systematic approach. Diagnosis and aetiology must be formally reviewed. About 20% of patients with apparently intractable epilepsy will be found

to have dissociative seizures. Other errors include mistaking partial-onset for generalised seizures and failing to identify a syndrome. Reassessment will also involve a thorough review of the history, in particular checking seizure semiology with the patient and informants. Video-EEG monitoring at this stage is strongly indicated if there is any doubt. Previous EEG data and neuroimaging should be reviewed. The possibility of non-compliance must be considered, together with aggravating factors (e.g. alcohol misuse) that might have been missed. A review of the medication history should address a number of questions for each drug that has been tried. Were adequate trials given? What was the maximum dose? Was there any response? Were there side effects and, if so, might these have been avoided?

Surgical treatment should be considered once no obvious problems or omissions emerge from a careful review of the treatment history. The selection of patients for surgery requires great care and is covered below. For most patients, however, resective surgery will not prove possible. Medical treatment in this group aims to optimise seizure control with the minimum of side effects. Overall, clinical trials of the newer antiepileptic drugs, given as add-on treatment, have generated remarkably similar results: around 40–50% of patients will experience a 50% reduction in seizure frequency but the chance of seizure remission is less than 5%. Reduced seizure frequency or severity may be of real benefit for some individuals, and for many the chance of remission, even if remote, is a good enough reason to give new drugs a try. However, some patients grow tired of repeated unsuccessful attempts, each one associated with side effects, and decide to remain on their 'tried and trusted' established treatment. In this situation it is important that patients are provided with information to allow them to make a balanced decision

between the risks posed by ongoing seizures and the likelihood of success with new treatment. There is little evidence favouring one add-on drug from another (French *et al.* 2004b; McCorry *et al.* 2004). Combinations of drugs that have different, or at least complementary, principal modes of action are a rational choice (Table 6.16). The most commonly cited example is a combination of lamotrigine and valproate, but there is no good evidence supporting this or any other combination. A benzodiazepine, usually clobazam, prescribed over a short period can be a useful adjunct to treatment in women with perimenstrual seizure clustering (catamenial epilepsy) or to cover significant events (e.g. travel, exams, social occasions).

Management of epilepsy in remission

Once seizures have been in remission for at least 2 years, antiepileptic drug withdrawal may be considered. Overall, the risk of relapse over the 2 years following withdrawal is approximately 40%, compared with around 20% if medication had been continued (Medical Research Council Antiepileptic Drug Withdrawal Study Group 1991; Berg & Shinnar 1994; Specchio *et al.* 2002). The most important predictor of relapse is diagnosis of an epilepsy syndrome. Relapse is very rare in benign rolandic epilepsy, moderately rare (25%) in absence epilepsy (Bouma *et al.* 1996) and almost inevitable in JME (Janz 1997). For patients with symptomatic or cryptogenic partial epilepsy the risk of relapse is intermediate, somewhere between 25% and 75%. In adults (excluding patients with JME) relapse is more likely if epilepsy began in adulthood and has an identified aetiology (50% increased risk compared with cryptogenic cases) (Berg & Shinnar 1994). Additional risk factors for relapse, listed in order of decreasing importance, include shorter duration of remis-

Table 6.16 Principal modes of action of antiepileptic drugs. (From McCorry *et al.* 2004 with permission.)

sion, taking two or more antiepileptic drugs, a history of myoclonic seizures, having seizures after the start of treatment, a history of tonic-clonic seizures of any type, and having an abnormal EEG (Medical Research Council Antiepileptic Drug Withdrawal Study Group 1991). These factors have been used to derive a predictive index (Medical Research Council Antiepileptic Drug Withdrawal Study Group 1993). However, probability figures may not help many patients (or their clinicians) weigh up risks and for many the chance of losing their driving licence outweighs any disadvantages of remaining on medication. It is widely presumed that if relapse occurs, then restarting previous treatment will achieve remission once again. Unfortunately, this is not so, a fact that adds a further degree of uncertainty to the decision. Up to 23% of patients who relapse after drug withdrawal may not regain freedom from seizures (Schmidt & Loscher 2005).

Surgical treatment of epilepsy

As described above, 20–30% of patients with epilepsy are unlikely to become seizure-free with medical treatment. For a proportion of this group, epilepsy surgery offers a real hope of remission. Patients with medial TLE form the largest group treated surgically. However, resections of extratemporal lesions, in particular operations involving the frontal lobe, are now more frequently performed. Additional procedures, conducted mostly in children, include hemispherectomy, multiple subpial transection and callosotomy.

The American Academy of Neurology has recommended that all patients with medically intractable localisation-related epilepsy be considered for surgery (Engel *et al.* 2003). Once at least two antiepileptic drugs have failed to control seizures, the chance of achieving remission with medical treatment alone is small. The point at which patients should be referred for surgical evaluation has not been defined but will depend to a large degree on the extent of disability. Given that this is likely to increase over time, and given also the risks of injury and sudden unexplained death in these patients, many believe that referral should be considered early, within 2 years of onset. It is useful to establish whether surgery is feasible at an early stage even for patients who are uncertain if they would undergo an operation. Patients will then be fully informed about the options available to them. Patients with identified lesions and those with the clinical syndrome of medial TLE are the most obvious candidates for early referral.

The aims of presurgical assessment are to identify an epileptogenic lesion and demonstrate, as far as possible, that the lesion can be removed without causing further, significant neurological or cognitive disability (Engel 1996). MRI will detect a structural lesion in over 80% of cases. If the lesion is potentially resectable, patients will usually proceed to video-EEG telemetry. Telemetry aims to establish that the seizures are indeed epileptic and also, through analysis of ictal EEG

and clinical semiology, that seizures arise from the identified lesion. Invasive methods of EEG recording, including foramen ovale and subdural grid electrodes, may be required when scalp recordings are inconclusive. Ictal SPECT and interictal PET may also help localise functional abnormalities, and PET ligand studies may identify lesions not seen with MRI, thereby providing a guide for depth EEG studies in MRI-negative cases. Neuropsychological testing, particularly of verbal and non-verbal memory function, provides additional lateralising information. Studies of normal cortical function are conducted to delineate areas that must be preserved during surgery. Intracarotid amobarbital injection with language and memory testing (Wada test) is used to identify the language-dominant hemisphere and to predict the likely effect of medial temporal lobe excision on memory function. Functional MRI is likely to have a growing role in presurgical cortical mapping.

Presurgical assessment involves the evaluation of a large amount of complex information by a highly specialised multidisciplinary team. The decision to recommend operation is based on the degree of concordance between the many different findings. Psychiatric assessment prior to surgery is essential. Surgery should almost certainly not be undertaken in patients with comorbid dissociative seizures, as these are likely to persist with disastrous consequences for outcome. Overall, a history of psychiatric disorder is not a contraindication for surgery. A judgement must be made in each case about the relative contribution of psychiatric morbidity and epilepsy to the patient's quality of life. If chronic psychiatric problems are felt to be the overriding source of disability, and are viewed as largely independent of ongoing seizures, then even a successful operation may have little impact on the patient's overall well-being. The burden of a failed operation will be more profound in such patients and this will also have to be taken into consideration. Postictal psychosis might be regarded as a relative indication for surgery. However, recent evidence suggests that this, and possibly interictal psychosis, are associated with bilateral medial temporal lobe dysfunction, and this should be considered when evaluating electrophysiological and imaging data [see Postictal disorders (Psychosis)]. A higher burden of proof that disease is unilateral may be required in such cases. Presurgical psychiatric assessment will also aim to identify those patients, principally those with a past psychiatric history, who are at highest risk of developing psychiatric disorder postoperatively. The transient, but sometimes severe, depressive reactions seen after surgery have been described under Risk factors for depression, earlier. Postsurgical follow-up arrangements must be vigilant for these sequelae, which carry a risk of suicide and require prompt treatment.

Surgery involves either the resection of an epileptogenic lesion or disconnection of pathways that serve seizure propagation (Polkey 2004). Temporal lobe surgery usually involves either an anteromedial temporal lobectomy (most common) or a more selective amygdalohippocampectomy.

A recent randomised controlled trial of mesial temporal lobe surgery found that 64% of patients who received surgery were free of disabling seizures (defined as seizures involving impaired consciousness) by 1 year compared with 8% of those treated medically (Wiebe *et al.* 2001). These results are almost identical to those of earlier uncontrolled surgical series that reported seizure-free rates of 68% at 1–2 years (Engel 1996). Significant improvements in quality of life only occur in patients who become seizure-free (Birbeck *et al.* 2002). The major determinant of outcome is pathological substrate. Patients with foreign tissue lesions (low-grade tumours of astrocytic or mixed origin including DNETs and focal cortical dysplasias) have a slightly better outcome than those with medial temporal sclerosis (Berkovic *et al.* 1995). This almost certainly reflects the fact that hippocampal sclerosis is bilateral in about 13% of cases and may be difficult to detect with MRI. A normal MRI predicts a poor (20% seizure-free) outcome (Berkovic *et al.* 1995; Hennessy *et al.* 2001). Serious complications, such as stroke or large visual field defects, occur in less than 2% (Behrens *et al.* 1997). Contralateral peripheral superior quadrant visual field defects following temporal lobectomy are usually small and not noticed by the patient. Minor word-finding difficulties are relatively common, especially after dominant hemisphere operations (Hermann *et al.* 1991). Postoperative cognitive, and particularly memory, function is determined primarily by the preoperative state. Deficits are more often detected in those with high preoperative functioning, while improvements may be seen in those functioning at a low level preoperatively (Chelune *et al.* 1991). Significant new memory deficits were seen in 5% of patients in the controlled trial mentioned above. Such deficits show the expected pattern of lateralisation (Morris *et al.* 1995; Martin *et al.* 1998). Stereotactically guided radiotherapy for epilepsy is a relatively recent technique that requires further evaluation, particularly with respect to possible longer-term effects including delayed radionecrosis (Regis *et al.* 2000).

There are few data concerning outcome following neocortical (temporal and extratemporal) resections (Engel *et al.* 2003). Overall, results appear less favourable, with seizure-free rates of around 50%. As might be expected, cases with a clearly identifiable lesion have a better outcome (63% seizure-free). Hemispherectomy or multilobar resection can be a dramatically successful procedure in infants or children with extensive disease confined to one hemisphere. Seizure-free rates of 60–80% are achieved, typically with improved functioning of the affected limbs postoperatively (Devlin *et al.* 2003). Multiple subpial transection involves disruption of intracortical connections while preserving the columnar pathways necessary for normal function. It is an effective treatment in Landau-Kleffner syndrome and may produce dramatic improvements in behaviour and language function (Robinson *et al.* 2001). The technique is also performed, usually in combination with limited resection, in adults with

partial onset seizures where adequate resection alone cannot be performed. A meta-analysis of over 200 such cases reported 95% seizure reduction in over two-thirds of cases, with new neurological deficits occurring in 22% (Spencer *et al.* 2002). Callosotomy, which involves resection of the corpus callosum (usually the anterior two-thirds), is a highly effective treatment for drop attacks (but not other seizure types) in children with severe symptomatic generalised epilepsy, e.g. Lennox–Gastaut syndrome. VNS may be an effective alternative in this situation (Hosain *et al.* 2000; Frost *et al.* 2001).

Vagal nerve stimulation

Vagal nerve stimulation was introduced as a treatment for epilepsy over 10 years ago (Schachter 2002). The procedure involves intermittent electrical stimulation of the vagus nerve via a stimulator inserted surgically over the anterior chest wall. The mechanism of action is unknown. Stimulation parameters are adjusted externally by means of a magnet and patients with auras can also trigger the device at seizure onset. VNS is usually considered for patients who prove unsuitable for epilepsy surgery but there is some evidence of efficacy in generalised epilepsy syndromes (Labar *et al.* 1999; Holmes *et al.* 2004; Ng & Devinsky 2004). Overall, a 50% reduction in seizure frequency is seen in approximately 30% of patients. Seizure remission rates are much lower, perhaps 5–10% (Helmers *et al.* 2003). Full benefit is often not achieved for several months. VNS is generally well tolerated: the main side effects are intermittent hoarseness of the voice and throat discomfort during stimulation but patients usually habituate to this. A reduction in anti-epileptic medication is often possible. Positive effects on mood and behaviour have been reported in some studies (Elger *et al.* 2000). Further work to define which patients are most likely to benefit from VNS is required.

Psychological treatment of epilepsy

A number of observations suggest that psychological approaches to seizure control should be helpful. People with epilepsy typically report that stress is an aggravating factor and it would seem logical to expect that helping people deal better with stress might be accompanied by a reduction in seizures. A small proportion of patients describe being able to wilfully precipitate seizures by focusing on mental experiences they have as part of their aura (Fenwick & Brown 1989). If mental processes can trigger seizures, might they not also be used to inhibit them? Many patients are indeed convinced they can modify or stop seizures through voluntary acts of will (Spector *et al.* 2001). The hope that the mind might be harnessed to control the brain has also been founded on the observation that people can learn to control certain aspects of EEG recordings using biofeedback techniques (Fenwick 1992). The numerous studies in this area have been reviewed

by Goldstein (1997) and are the subject of a Cochrane review (Ramaratnam *et al.* 2005). Studies have been small and poorly designed, and as yet there is no good evidence of efficacy. However, several areas deserve further investigation.

Cognitive-behaviour therapy may target background factors such as anxiety and coping skills. More specific interventions involve a variety of cognitive and relaxation techniques that patients can engage when they experience an aura or prodromal symptoms. Such cued countermeasures, conceived of as the psychological opposite of a patient's habitual experience at seizure onset, may be tailored to match individual patients' symptoms. For example, if the patient typically feels drowsy prior to a seizure, the countermeasure might aim to heighten arousal. Heightened arousal might also have a more general application in patients with epilepsy: an inverse correlation between autonomic arousal and contingent negative variation, a marker of cortical excitability, has been demonstrated and provisionally mapped to a distributed network of brain regions including thalamus, cingulate cortex, sensorimotor cortex and insula (Nagai *et al.* 2004a). In a small treatment study, the same group have reported a method of training patients to achieve heightened levels of autonomic arousal using biofeedback from (reduced) galvanic skin resistance (Nagai *et al.* 2004b). Patients were instructed to use the technique in response to seizure warnings. Six of nine patients achieved a 50% reduction in seizure frequency over a follow-up period that was limited to 3 months. These studies suggest a plausible physiological mechanism of action but, like many before them, provide only weak evidence that psychological treatment is effective.

Non-pharmacological approaches to treatment, including psychological ones, that give patients a sense of self-control and avoid toxic side effects are obviously an attractive prospect. Many clinicians would like to be able to recommend such treatment, but large well-designed clinical trials are needed to establish their efficacy.

Status epilepticus

Status epilepticus is usually defined as a condition in which epileptic activity persists for 30 minutes or more (Shorvon 2001; Walker & Shorvon 2004). Convulsive status is the term used to describe the status form of tonic-clonic seizures. The clinical features of non-convulsive status have been described under Non-convulsive status epilepticus. About 5% of adults with epilepsy will experience at least one episode of status. In children, the proportion is higher (25%). Common precipitants include drug withdrawal, intercurrent illness and metabolic disturbance. However, most status arises in people who have no prior history of epilepsy and is due to acute cerebral insult. The most common causes in this situation are CNS infection, trauma, stroke, hypoxia, metabolic disorders and alcohol withdrawal.

Convulsive status is a medical emergency. The risk of irreversible brain damage increases progressively from about 1 hour after onset and it is imperative that if seizures are not controlled by this time, anaesthesia should be instituted. For patients with established epilepsy, the duration of their habitual seizures will guide the decision about when to start treatment. As a general rule, treatment should be instituted after 5–10 minutes of continuing seizure activity. In a community setting, buccal midazolam (adult dose 10 mg) or rectal diazepam (adult dose 10–30 mg) may be given by carers or paramedics (both drugs can be repeated after 15 minutes). In medical settings, the first-line treatment is lorazepam (adult dose 4 mg) given as an intravenous bolus. An adequate airway must be secured and oxygen should always be given. The ECG should be monitored. An intravenous line is required for fluid replacement and drug administration. Blood should be taken for blood gases, glucose, renal and liver function, calcium and magnesium, full haematological screen (including platelets), clotting profile and antiepileptic drug levels. If hypoglycaemia is suspected, 50 mL of 50% glucose should be given immediately by intravenous injection. If there is suspicion of alcoholism or any other state of compromised nutrition, thiamine 250 mg should also be given. This is especially important if glucose has been administered (because of the heightened risk of Wernicke's encephalopathy). The timing of further investigations, including neuroimaging, will depend on circumstances.

If the initial bolus of lorazepam is ineffective, it may be repeated after 10 minutes, but second-line treatment should be considered at this point. Phenobarbital and phenytoin are the drugs of first choice at this stage. If the episode has been precipitated by withdrawal from antiepileptic medication, this should be restarted. If seizures continue despite these measures, the patient should be transferred to intensive care and anaesthesia instituted. Cerebral damage is caused, at least partly, by the direct effects of ongoing seizure activity. EEG monitoring is therefore critical at this stage.

Absence status is a benign condition and does not require aggressive treatment. Episodes are usually terminated quickly with benzodiazepines. There is no good evidence that aggressive treatment is warranted in complex partial status. The emphasis is instead on early recognition and treatment is with benzodiazepines. Some patients have recurrent episodes that are heralded by severe clusters of seizures. These can often be treated at home with oral benzodiazepines.

Sudden death in epilepsy

It has long been suspected that people with epilepsy are at risk of sudden unexplained death but the nature and extent of this risk were unknown until relatively recently. By 1997, Annegers was able to estimate a near 40-fold increased risk

in people with epilepsy compared with the general population. Quantification of the risk is clearly of the utmost importance in counselling patients and in making treatment decisions. The overall annual incidence of SUDEP has been estimated as 0.35 per 1000 patients (Ficker *et al.* 1998), but in patients with severe intractable epilepsy it may be much higher. For example, in patients being assessed, or waiting, for epilepsy surgery an annual incidence of 1 in 100 has been reported (Dasheiff 1991). Among patients attending a tertiary care service a representative figure would be about 1 in 250 (O'Donoghue & Sander 1997; Tomson *et al.* 2005).

That the overwhelming majority of these deaths are seizure related is no longer doubted. The mechanisms are not yet clear and are the subject of intense investigation (Nashef *et al.* 2007). Progress has been made, however, and it appears that apnoea is an important mechanism in many cases. Asystole is also likely to be important, independent of respiratory arrest, and may be related to the well-documented but rare occurrence of ictal bradycardia (see Differential diagnosis of epilepsy, Syncope, earlier in chapter).

Risk factors have been investigated in observational series and case-control studies. Factors including frequent seizures, tonic-clonic seizures, taking two or more antiepileptic drugs, recent antiepileptic drug withdrawal, and never having received drug treatment have consistently emerged as important (Nashef & Langan 2004; Tomson *et al.* 2005). There is some evidence that carbamazepine may be over-represented but this finding, and the association with polytherapy, may be surrogate markers for epilepsy severity. However, antiepileptic drugs, particularly polytherapy, are sometimes known to exacerbate seizures and this may be a factor (Perucca *et al.* 1998). Most recently, based on an analysis of antiepileptic drug levels in hair samples, Williams *et al.* (2006) have provided evidence that erratic drug compliance may also be important. Most cases of SUDEP are unwitnessed and occur at night. From this and other observations it has long been suspected that lack of supervision at night might be a risk factor (Nashef *et al.* 1995). This was confirmed by the most recent case-control study: sharing a bedroom with someone capable of giving assistance and the use of listening devices were both significant protective factors (Langan *et al.* 2005).

Several important clinical implications arise from these findings. Seizure prevention, particularly prevention of tonic-clonic seizures, must be the aim of treatment. Abrupt changes in medication should be avoided and any recently introduced drug that exacerbates seizures should be withdrawn. Patients must be warned about the dangers of not taking medication regularly. The findings also emphasise the importance of first aid advice. Patients should be attended to quickly during a seizure: simple measures such as positioning them and stimulating them if they are not breathing may be life-saving.

Patient education

Providing information for a patient newly diagnosed with epilepsy is a major part of treatment. The points that need to be covered are listed in Table 6.17. Information sheets published by the epilepsy societies are an invaluable resource and should be made readily available to patients and their families. Epilepsy is poorly understood by the general public and still carries the stigma of mental illness, and even of supernatural phenomena (Caveness & Gallup 1980; Jacoby *et al.* 2004; Diamantopoulos *et al.* 2006). The nature of epilepsy must therefore be carefully explained. Advice about treatment and prognosis will obviously be dictated by aetiology and syndrome diagnosis. For most patients, the good news is that medication is highly likely to stop their seizures and investigations will have ruled out any sinister, progressive underlying disease. The clinician will often have a fairly good idea from the start about the likelihood that medication will need to be continued long term. It is as well to raise this difficult issue early on. As treatment is started, discussion must cover the likely benefits and side effects of treatment. Patients need to be warned about hypersensitivity reactions but also reassured that if symptoms of dose-related toxicity develop, these can readily be dealt with by adjusting the dose and slowing the rate of dose increase. Patients need to be aware of the possibility of drug interactions. It is important to stress that medication must be taken regularly, both to be effective and because of the risks of withdrawal seizures. Advice about exacerbating factors needs to be given. Sleep deprivation should be avoided as should excessive alcohol consumption. In relation to the latter point, one or two units, once or twice a week, is probably safe (Hoppener *et al.* 1983). Patients and their carers will often be very worried about the risks of accidental injury. In general, they

can be reassured that the risk is small. First aid advice (protection from injury, recovery position, when to call for help) should be provided for the patient and carers. Taking a bath unsupervised should be avoided: showers are safer and scald injuries can be prevented by thermostatic control of the hot water. Most sports are safe with a few obvious exceptions (e.g. scuba diving, rock climbing, skydiving). Swimming is generally regarded as safe if supervision is available. If seizures do not remit, patients will gradually come to conclusions about what level of risk is acceptable in trying to live as normal and independent a life as possible. How frequent seizures are and whether they are preceded by a useful warning will obviously be factored into the decision. A few patients may choose to live rather recklessly, but this may seem preferable to being overly cautious and over-protected. The issue of SUDEP needs to be discussed sensitively. A number of the special issues relating to women have already been mentioned (see Patient characteristics, earlier). These include possible drug interactions with the oral contraceptive pill, considerations relating to pregnancy, and the increased risk of bone disease in postmenopausal patients (Crawford *et al.* 1999).

Driving is an important issue that must be covered at the time of diagnosis. Driving laws vary around the world. In the UK, regulations are regularly updated. At present, an ordinary driver's licence may be granted to an individual if free of seizures for 1 year or if seizures have occurred only during sleep for at least 3 years. An additional condition is that allowing the patient to drive must not be likely to endanger the public. Thus, other factors such as neurological or psychiatric comorbidity and medication effects must be considered. Special consideration may be given following a single seizure if provoking factors are clearly identified and non-recurrent. Additional restrictions apply to a commercial drivers licence, in which case a seizure-free period of 10 years (off medication) is required, and there must be no identifiable ongoing liability to seizures. The licensing authority recommends that where medication is being withdrawn after seizure remission, the patient should not drive during the period of withdrawal and for 6 months afterwards. However, there is no requirement that the driving licence be surrendered.

Epilepsy may have far-reaching effects on education and employment prospects. Some jobs may not be possible, for example those that require a driving licence or entail sole responsibility for the safety of others, but people with epilepsy are undoubtedly subject to discrimination (Chaplin 2005). Interventions to educate employers and teachers can be extremely effective in this situation.

Treatment of psychiatric disorder in epilepsy

Patients with chronic epilepsy often represent complex and challenging management problems. Some difficulties will

relate directly to ongoing seizures and their treatment. Others will be more obviously 'psychiatric': depression or psychosis for example, or social problems related to education, employment, interpersonal relationships or care provision. Yet a simple division into 'neurological' and 'psychiatric' is seldom possible or desirable. A management plan will need to consider the type of epilepsy, its underlying cause and its current and potential treatment, all of which must be set within the context of psychiatric diagnosis, cognitive function and capacity for independent living, social circumstances and support networks. The causes, treatment and outcome of each set of problems are mutually dependent. Management requires a holistic approach from a multi-disciplinary team that might include nurse specialists, psychologists, occupational and speech therapists, physiotherapists, social workers and doctors. Every member of the team should have special knowledge and experience of epilepsy. The service should have links with the epilepsy societies and with support groups for patients and carers. Liaison with primary care and with other specialist services will be essential if complex management plans are to have any chance of success.

Assessment will naturally involve a review of the epilepsy history and how this relates to the psychiatric presentation. Two aspects of the neurological history are particularly important. The first concerns the temporal relationship between seizures and psychiatric disorder. The clinician must assess whether the two are related and, if so, whether psychiatric symptoms are ictal, postictal or interictal. This distinction has important implications for treatment and prognosis. Psychotic symptoms are a good example. Ictal psychotic symptoms are simply an expression of epilepsy. Their importance lies primarily in recognising them as epileptic and differentiating them from functional psychiatric disorder: seizure control will be the focus of treatment and neuroleptics have no role. If a diagnosis of postictal psychosis has been made, symptoms will be expected to resolve spontaneously in a few days. Admission and sedation with benzodiazepines may be required but neuroleptics usually will not. In the longer term, recurrence may be prevented with better control of the epilepsy. However, if the diagnosis is one of interictal psychosis, then management, including pharmacological and non-pharmacological measures, will be along lines that would be familiar to a general psychiatrist treating a patient with schizophrenia.

The second particularly important aspect of the neurological history concerns treatment history. Antiepileptic drugs are a common cause of cognitive, behavioural and psychiatric morbidity in people with epilepsy. Mood disturbance and psychosis may occur as a direct consequence of any antiepileptic drug and any changes in treatment that preceded the onset of psychiatric symptoms may implicate a specific cause. A more common problem concerns the dose-related

toxic effects of drugs on the CNS, which may present with cognitive slowing, underperformance at school or work, and any number of behavioural problems. Polypharmacy is particularly associated with this clinical picture. Overly aggressive treatment of epilepsy may also sometimes cause a worsening of seizure control with further effects on psychosocial functioning. Optimising the treatment of the patient's epilepsy – achieving control of seizures with the minimum of side effects – is often one of the most important aspects of 'psychiatric' treatment.

In general, the psychiatric disorders associated with epilepsy are treated as they would be if epilepsy were not present. In the absence of any well-designed treatment trials, treatment is based on opinion and experience. This is clearly a deficiency, but it is reassuring that several decades of clinical experience have not highlighted any striking differences between the outcome of psychiatric treatment in epilepsy and that which might be expected in general psychiatric practice. As in other areas of psychiatry, treatment may involve medication, psychological treatment and social measures. The indications for each are much as they would be in the absence of epilepsy.

Psychotropic medication in epilepsy

The most frequently cited treatment problem is that most psychotropic drugs have the potential to exacerbate seizures. However, this has been overstated in the past. Useful reviews of this issue have been provided by McConnell and Duncan (1998), Alldredge (1999) and Pisani *et al.* (2002). Concern about the proconvulsant effect of psychotropics stems from a number of sources, including studies in animals, reports of adverse reactions to drug monitoring agencies (including reports of seizures after overdose), and data concerning the incidence of seizures in preclinical and clinical trials. It is extremely difficult to draw any clear recommendations for clinical practice from these data. Clozapine is the one drug undoubtedly associated with a significant risk of seizures. As with other psychotropic drugs the proconvulsant effect of clozapine is dose related; as a guide, seizures may be expected in 2–3% of patients (with no prior history of epilepsy) with doses in the range 300–600 mg daily (Devinsky *et al.* 1991). With this exception, the incidence of seizures in non-epileptic individuals treated with therapeutic doses of antidepressants and antipsychotics is very low, well below 1% (Alldredge 1999). Comparisons between individual drugs cannot be made conclusively, but there is some suggestion that the more recently introduced antidepressants are marginally less proconvulsant than tricyclics. However, none of these data reveal how significant the risk of seizures is when psychotropics are given to people with epilepsy. It is quite reasonably assumed that patients with epilepsy will be more sensitive to proconvulsant effects. However, most people with epilepsy are of course taking antiepileptic drugs and this will presumably have a moderating effect. Large

well-designed trials of psychotropics in patients with epilepsy would be required to answer this question and as yet have not been done. In relation to antidepressants, small trials have reported no exacerbation of seizures with amitriptyline and nomifensine (Robertson & Trimble 1985), fluvoxamine (Harmant *et al.* 1990), paroxetine (Andersen *et al.* 1991), and citalopram, mirtazapine or reboxetine (Kuhn *et al.* 2003). In a report of 97 patients treated with sertraline, increased seizure frequency occurred in six patients, one definitely so, the remaining five only possibly and transiently (Kanner *et al.* 2000). Two studies have in fact described *improvement* in seizure control, one with fluoxetine (Favale *et al.* 1995) and one with citalopram (Specchio *et al.* 2004). While it seems improbable that antidepressants have a clinically useful antiepileptic action, these findings serve to emphasise that, in therapeutic doses, antidepressants are most unlikely to have any detrimental effect on seizure control. There are no controlled trials of neuroleptics in patients with epilepsy. Pauig *et al.* (1961) reported improvement in seizure frequency, or no change, in two-thirds of 100 patients with epilepsy treated with thioridazine. There are very few reports of lithium treatment in patients with epilepsy. Lithium is markedly proconvulsant in overdose but is probably not associated with any change in seizure control at therapeutic doses.

Treatment of depression and anxiety

In light of the data reviewed above, clinicians should not hesitate to prescribe antidepressants for patients with epilepsy if they would otherwise be indicated. Recommended drugs, drawn from the reviews cited above, include citalopram, escitalopram, fluoxetine, mirtazapine, moclobemide, nefazodone, paroxetine, reboxetine, sertraline, trazodone and venlafaxine. Tricyclic antidepressants (e.g. amitriptyline, clomipramine, dothiepin, lofepramine, imipramine, nortriptyline and trimipramine) are associated with a higher risk of seizure exacerbation. They should be regarded as second-line choices, but are by no means contraindicated in the presence of epilepsy. The proconvulsant effect of all these drugs is dose related. A sensible approach is therefore to start treatment at relatively low doses and to increase the dose slowly. As with antidepressant treatment outside the context of epilepsy, choice of drug and treatment failure will primarily be influenced by side effects other than any effect on seizure control. In exceptional cases, where an exacerbation of seizures does occur, it is almost always of a minor degree and an alternative drug better tolerated by that individual can usually be found. There are many potential interactions with antiepileptic drugs, especially with the hepatic enzyme-inducing drugs, and these should always be checked before prescribing. In practice there are few clinically significant interactions (i.e. interactions that involve commonly prescribed combinations or are of large effect-size). More common examples include the following: fluoxetine and sertraline may increase serum levels of phenytoin, and

sertraline may cause a rise in lamotrigine levels. Electroconvulsive therapy is an effective and safe treatment for severe depression in epilepsy (Lunde *et al.* 2006). Seizure induction is usually possible without reduction of antiepileptic drugs and there is usually no discernible effect on seizure frequency.

The profound impact that epilepsy may have on almost every aspect of life has been mentioned many times in this chapter. The frustration of restricted opportunities in work and leisure, difficulties with personal relationships and the stigma, both real and perceived, attached to seizures all contribute to the development and maintenance of depression. Psychotherapeutic approaches are as important in epilepsy as they are in general psychiatry. As in other areas of psychiatry, the type of therapy is possibly not as important as the individual qualities of the therapist. In this respect, therapists with experience of epilepsy will have a number of advantages: familiarity with the practical issues likely to be involved (e.g. treatment and safety issues, work and driving restrictions) and being able to place a patient's difficulties in the context of other cases will facilitate an empathic therapeutic relationship. Epilepsy nurse specialists can play an invaluable role in providing patient and carer education, longer-term support and liaison between the different agencies often involved in caring for the most vulnerable patients (Ridsdale *et al.* 1999). Cognitive-behaviour therapy may have a special place in the management of 'seizure phobia', a term used to describe the not uncommon situation in which a patient is more disabled by fear of having seizures than by the seizures themselves (see Anxiety, earlier in chapter). Specific therapeutic strategies might include challenging negative cognitions and cognitive schema concerning epilepsy, and seeking to modify safety and avoidant behaviours (Newsom-Davis *et al.* 1998).

Treatment of psychosis

Most cases of interictal psychosis will require treatment with neuroleptic drugs. Drugs regarded as being associated with a low risk of seizure exacerbation include sulpiride, haloperidol, risperidone and trifluoperazine. Amisulpiride, olanzapine and quetiapine are regarded as having a higher risk but this is probably marginal and the choice of treatment will be dictated primarily by consideration of the more general side-effect profile of the drug. Depot neuroleptics should probably be avoided because although the risk of seizure exacerbation is low, if there is an exacerbation of seizures, the offending drug may not be quickly withdrawn. A 'start low, go slow' approach is again sensible. As with antidepressants, there are a large number of potential interactions with antiepileptic drugs but these are generally not clinically significant. The treatment of refractory psychosis poses a difficult problem because of the marked proconvulsant effect of clozapine, the only drug with established efficacy in this situation. However, Langosch and Trimble (2002) have described

six patients with refractory psychosis and epilepsy who were successfully treated with clozapine, without exacerbation of seizure frequency. Such treatment should be initiated in hospital. The most important interactions between antiepileptic drugs and clozapine are pharmacodynamic: if the patient is taking carbamazepine, this should probably be replaced because of the potential synergistic risk of agranulocytosis. Lamotrigine, or one of the newer antiepileptic drugs, may be preferable to valproate because of the likelihood of weight gain and sedation with the latter.

As already mentioned, postictal psychosis does not generally require treatment with neuroleptics. The marked agitation often seen in this disorder may necessitate hospital admission and symptomatic treatment (sedation) with benzodiazepines. If antipsychotic agents are used, it is very important that they are withdrawn promptly once symptoms have resolved. A small proportion of patients will eventually progress from postictal to chronic interictal psychosis but there is no evidence to support prophylactic use of antipsychotics to prevent this progression.

Treatment of dissociative seizures

The most important, and often the most difficult, step in managing patients with dissociative seizures is engaging them in psychiatric treatment. How the diagnosis is communicated to the patient is critical. Shen *et al.* (1990) and Mellers (2005) have discussed this issue in some detail (Table 6.18). Patients are obviously extremely sensitive to any suggestion that they are feigning their symptoms. A description of dissociation and of any likely aetiological factors to emerge in the history will help patients understand what the disorder is and why they have it (see Dissociative seizures, earlier). Dissociative seizures often reduce in frequency and may even stop after the patient is given the diagnosis (Farias *et al.*

Table 6.18 Presenting the diagnosis of dissociative seizures.

<i>Explanation of the diagnosis</i>
Reasons for concluding that the patient does not have epilepsy
What the patient does have (describe dissociation)
<i>Reassurance</i>
That patient is <i>not</i> suspected of 'putting on' the attacks
That the disorder is very common
<i>Causes of the disorder</i>
Triggering 'stresses' for seizures may not be immediately apparent
Any specific aetiological factors relevant
Importance of maintaining factors
<i>Treatment</i>
Suggest that seizures usually improve after the correct diagnosis is made
Caution that antiepileptic drug withdrawal should be gradual
Limited role of psychotropic medication
Describe psychological treatment

2003). This is especially likely when seizures are of recent onset. Many clinicians believe that suggestion may be an important adjunct to this effect. Patients should be cautioned not to stop antiepileptic drugs suddenly. Carers should be involved in these discussions, with the patient's consent, as early as possible.

Reuber *et al.* (2005) have recently provided a comprehensive review of specific approaches to treatment. Treatment should aim to control seizures but this may be achieved without any real improvement in overall outcome. Background psychosocial factors must also be addressed. Patients with dissociative seizures often have a history of depression and anxiety disorder but these symptoms are usually mild and pharmacotherapy plays a relatively minor role. The mainstay of treatment is usually some form of psychological therapy. Many approaches have been advocated but there have been no controlled treatment trials. The early literature includes several compelling reports of psychodynamic approaches, often in patients with traumatic childhood experiences. Operant behavioural programmes using simple reward systems may be very effective in patients with learning disability. Variations of therapy based on psychodynamic, insight-oriented and group-based methods are undoubtedly widely practised and require further evaluation.

The paroxysmal nature of dissociative seizures lends itself to a cognitive-behaviour approach modelled on that developed in panic disorder and post-traumatic stress disorder. Rusch *et al.* (2001) combined such approaches with psychodynamic methods in a series of 33 patients, one-third of whom had a relatively short duration of illness (less than 1 year); 63% were free of seizures at the end of treatment. In a smaller series of 20 patients with a longer history of seizures, Goldstein *et al.* (2004) reported more modest improvement in seizure control (20% seizure-free) but significant gains in work and social outcome.

The most difficult group to treat is undoubtedly those patients with coexistent epilepsy. In many cases dissociative seizures are the major source of disability but distinguishing between the different types of seizures may be very difficult. Showing patients and carers videos obtained during telemetry is invaluable but the situation often changes over time; semiology changes, new seizures appear and telemetry may have to be repeated. A significant proportion of patients continue to have seizures despite intensive treatment. A pragmatic approach in such cases, as in other somatoform disorders, is to offer long-term follow-up to provide support for the patient and family and to limit the costs and morbidity associated with further unnecessary investigations and medical interventions.

Intracranial Infections

Michael D. Dilley¹ and Simon Fleminger²

¹Soho Centre for Health and Care, London

²Maudsley Hospital, London

Intracranial infections are usually the province of the neurologist or general physician but must occasionally be considered in the differential diagnosis of psychiatric patients. HIV/AIDS is of particular importance, likewise cerebral syphilis which, though rare, has shown an increasing incidence recently and has crucial treatment implications. These are dealt with in some detail, also certain encephalitic illnesses in which diagnostic confusion can arise. More space is devoted to encephalitis lethargica than its present-day incidence warrants, because of the important lessons that were learned for psychiatry during outbreaks of the disease. Meningitis, cerebral abscess and other nervous system infections are dealt with very briefly.

Acquired immunodeficiency syndrome

The appearance of AIDS on the medical and social scene, over 25 years ago in the early 1980s, has been followed by worldwide spread of the disease and escalating numbers of persons affected. Significant impact has been made on the prevalence of the disease, particularly through the use of highly active antiretroviral treatment (HAART), and knowledge about the effects of the virus as well as investigative methods to assess this have progressed significantly since the first recognised cases. Nonetheless, the virus is still rife in the USA and Europe, although its impact is far greater in sub-Saharan Africa and other developing countries. Worldwide, over 40 million adults and children are living with HIV or AIDS. There are an estimated 8500 deaths from the disease daily – two-thirds of these are in sub-Saharan Africa – and greater than 20 million have already succumbed to the disease (UNAIDS 2006).

In Western and Central Europe in 2006, there were up to 970 000 people living with the virus. During the period 1998–2005, the rate of new diagnoses nearly doubled, from 42 to 74 cases per million. The most rapid increase was seen in the

UK, where in 2005 there were 7700 new diagnoses (Health Protection Agency 2005). Figures from the USA are many times in excess of this, with only seven countries worldwide estimated to have more cases. A cumulative total of some 1 150 000 HIV or AIDS cases had been reported in the USA from the start of the pandemic to 2004 (Centers for Disease Control 2006a). Altogether in 2006 reports suggest 25 million infected adults in sub-Saharan Africa, 7.8 million in South and South-east Asia, and 2 million in Latin America and the Caribbean (UNAIDS 2006).

Problems associated with the disease include not only its devastating clinical manifestations and their economic cost, but also the cultural and social problems that must be tackled in attempts to limit its spread. For the first time in a worldwide epidemic it has been necessary to try to change fundamental aspects of human behaviour by education and the dissemination of information. Moreover, this centres on topics as sensitive as sexual practices and the control of risk-taking behaviour among persons addicted to drugs. A particularly disturbing aspect concerns the risk of transmission to children born to infected women; the proportion of females has slowly risen and is particularly high, approaching 60%, in Africa, some 13.3 million people. Added difficulties arise from the stigma attached to the disease and the fear engendered among populations at special risk, particularly men who have sex with men. This is fuelled by the ever-present risk of transmission from infected but asymptomatic individuals.

Epidemiology and groups at risk

The disease was first recognised in 1981 when cases of *Pneumocystis carinii* pneumonia (PCP) and Kaposi's sarcoma were reported from California and New York in previously healthy men who were both homosexual and immunocompromised. The first UK cases were recognised soon afterwards. With

hindsight, however, the disease had existed in the USA since at least 1978, and analysis of stored serum samples has indicated that the virus was entering the drug-injecting population in the mid-1970s (Des Jarlais *et al.* 1989). The origins of HIV have been the subject of intense debate. It has been reported that lentiviruses most closely related to HIV-1 have been isolated in chimpanzees, particularly the subspecies *Pan troglodytes troglodytes*, native to western equatorial Africa. Interspecies transmission is hypothesised to have occurred prior to 1940 (Sharp *et al.* 2001).

The subgroups of the population mainly affected differ with geographical location. In Western Europe, North America and Australasia, men who have sex with men are predominantly affected, followed by injecting drug users and heterosexual contacts with infected persons. On the west coast of America, the majority of HIV-infected persons are men who have sex with men, whereas on the east coast there is a higher prevalence among intravenous drug users. More than half of the estimated 200 000 drug injectors in New York in the late 1980s were infected with HIV, and appeared to be the principal source of heterosexual and perinatal transmission (Des Jarlais *et al.* 1989). In the UK, the prevalence varies among drug users, from around 7% in London to 20% in Edinburgh (Stimson 1995), a significant decrease from the previously reported 55% Edinburgh (Adler 1987). In Italy and Spain drug injection accounts for over two-thirds of the cases of AIDS, whereas in sub-Saharan Africa the commonest mode of transmission is heterosexual intercourse (UNAIDS 2006).

Figures on cases reported between 2001 and 2004 in the USA and the UK show that male homosexual transmission is clearly the commonest route. In the UK, a large proportion of infections through heterosexual intercourse are thought to derive from infections acquired abroad, particularly from African countries. Transmission via contaminated blood products was recognised from 1983, largely stemming from contaminated pooled factors VIII and IX given to haemophiliac patients. Mother-to-infant transmission in the UK may be due in large part to mothers who acquired the infection in Africa.

The virus disproportionately affects racial and ethnic minorities. In the USA, for example, during the period 2001–2004, some 50% of AIDS diagnoses were in the African-American population and 20% among the Hispanic community. In 2004, the rate of new diagnoses was seven times higher in African-American men and a startling 21 times higher among African-American women compared with their white counterparts (Centers for Disease Control 2006a).

The largest concentration of infection in the UK is in London and the South-east (Health Protection Agency 2006), accounting for 56% of all cases reported in 2005. However, there has been a gradual increase in diagnoses in other regions, including areas where HIV infection had been pre-

viously rare (Health Protection Agency 2006). While transmission between men who have sex with men remains the commonest group infected (around one-third of new diagnoses), persons infected in sub-Saharan Africa are now the group most affected by HIV in the UK. Research reported from the South-east and the Midlands suggests that the fear of discrimination and stigma associated with diagnosis are significant factors that preclude UK Africans from seeking serum testing (Elam *et al.* 2006). In the UK, levels of HIV and other sexually transmitted infections remain high in the population of men who have sex with men and new diagnoses have increased by 50% since 2000 (Health Protection Agency 2006). This has provoked fresh calls for prevention and education strategies targeting this risk group (Elford *et al.* 2005). Indeed, it is concerning that knowledge regarding HIV is deteriorating in general. In 2005, only 70% of surveyed Londoners were aware that HIV was transmitted by unprotected sexual intercourse compared with 91% in 2000 (National AIDS Trust 2006). Furthermore, in the UK the number of individuals living with HIV who have not been tested and are unaware of their status has been estimated as around one-third. This obviously not only impacts on the risk of transmission but also the potential benefits of treatment for this group (British Medical Association 2006).

The virus

The virus responsible for AIDS was isolated in 1983. It was first named lymphadenopathy-associated virus (LAV) in France and human T-cell lymphotropic virus type III (HTLV-III) in the USA, but by common consent is now termed human immunodeficiency virus (HIV). The overwhelming majority of cases worldwide are caused by HIV-1, although the related HIV-2 (LAV-2, HTLV-IV) has proved to be responsible for a similar AIDS presentation, principally among West Africans. HTLV-I is responsible for epidemics of tropical spastic paraparesis that may be transmitted sexually.

Related viruses in animals include visna virus in sheep and caprine arthritis encephalitis virus in goats, which lead to neurodegenerative disorders. Of particular interest are the simian immunodeficiency viruses (SIVs). Strains of SIV (SIVsm) most closely resembling HIV-2 and likely to be related viruses have been found in the wild in sooty mangabeys (*Cercocebus atys*) native to West Africa and also in several macaque monkeys in captivity in North America. HIV-2 is only endemic in West Africa and it seems likely that transmission between monkeys and humans has occurred there. Strains of SIV from chimpanzees (SIVcpz) resemble HIV-1, and despite initial uncertainty it is now clear that this is the likely origin of HIV-1. Cross-species transmission is hypothesised to have occurred through exposure to chimpanzee (and sooty mangabey) blood and mucosal secretions during hunting or when eating raw contaminated 'bush meat' (Robinson 1999; Sharp *et al.* 2001). These viruses are lenti-

viruses (i.e. slow to replicate and produce pathological effects) in the general class of retroviruses. Retroviruses have the unique characteristic of replicating by entering host cells, then using the enzyme reverse transcriptase to integrate their own genetic material into the DNA of the host cell nucleus. This continues to manufacture the virus until the cell dies, resulting in persistent infection. HIV-1 and HIV-2 resemble each other under the electron microscope but differ in the molecular weight of their constituent proteins. HIV infects cells that bear the CD4 surface receptor, using a glycoprotein on its surface (gp120) for the initial interaction. CD4 is the primary receptor for HIV and is found on monocytes, macrophages, eosinophils, dendritic cells and microglial cells in the central nervous system (CNS) as well as a subset of T-helper lymphocytes (T4 cells). Experiments have shown that CD4 receptors on the cell surface of non-human cell lines are insufficient to allow entry of HIV; subsequently, the existence of coreceptors was hypothesised and investigated. In 1995–1996, it was reported that members of the chemokine receptor family, specifically CCR5 and CXCR4, could co-facilitate the entry of HIV-1 into CD4⁺ cells (Rowland-Jones 1999).

Once inside the cell, reverse transcriptase carried in the genome of the virus catalyses the production of a DNA copy of the single-stranded viral RNA. This migrates to the nucleus of the cell and becomes integrated into its genome. The integrated DNA copy is called a 'provirus'. Thereafter it may exist in latent form without pathogenic effect, reproducing along with the cell, or it may change to become productive and cytopathic. Such change involves the production of new viral RNA, the assembly of viral proteins that are toxic to the cell, and the budding of new virus from the surface of the cell to infect others. In individuals treated with HAART, reservoirs of latent provirus in quiescent CD4 cells have taken on new importance, as they are instrumental in preventing eradication of the virus.

Retrovirus replication is prone to errors and subsequently mutations; on average, 1–10 errors per genome per round of replication occur. This results in either replication-incompetent virions or mutations that cause drug resistance. The hallmark of active HIV infection is the gradual depletion of T4-helper lymphocytes in the blood, with correspondingly disastrous impairment of the body's immunological competence. Infection of macrophages and microglia leads to a further range of complications involving the nervous system directly as described below.

Natural history and clinical signs of HIV infection

Infection with HIV-1 follows a characteristic course, but with wide variation in the timing of the various stages.

Acute 'seroconversion' illness. This affects 50–90% of people, setting in 2–6 weeks after exposure and probably reflecting

direct invasion by the virus. Symptoms often take the form of a mild glandular fever-like illness, with fever, myalgia, sore throat, lymphadenopathy and a maculopapular rash, generally subsiding within 1–2 weeks. A longer duration of seroconversion illness with more severe symptoms may predict more rapid progression to AIDS (Vanhems *et al.* 2000). More severe manifestations include mucocutaneous ulceration, or in 10% reflect nervous system invasion with aseptic meningitis accompanied by cranial nerve palsies particularly of the fifth, seventh and eighth nerves; myelopathy or neuropathy; encephalitis with delirium (McArthur 1987; Malouf *et al.* 1990), acute disseminated encephalomyelitis, transverse myelitis, polymyositis or a transient acute confusional state sometimes with seizures (Carne *et al.* 1985). Fever and malaise have been shown to have the highest sensitivity for clinical diagnosis of acute HIV-1 infection, while weight loss and oral ulceration have the highest specificity (Hecht *et al.* 2002).

Early during this period, viral nucleic acid can be detected in the blood, cerebrospinal fluid (CSF) and most organs of the body. A transient lymphopenia affects both CD4 and CD8 lymphocyte subsets (T-helper and cytotoxic cells, respectively), followed a week or two later by lymphocytosis. Viral replication is of the order of 100 million copies of HIV-1 RNA per millilitre during this acute infection stage and virus seeds to tissue reservoirs alongside destruction of CD4⁺ T lymphocytes in gut lymphoid tissue. Towards the end of this stage HIV-1 antibodies begin to appear in the serum, conventional antibody tests becoming positive after 2–6 weeks or occasionally after a delay of several months. Prior to this, detection of plasma HIV-1 RNA may aid diagnosis.

After the initial high numbers of copies, viraemia declines significantly to a level referred to as the viral setpoint, a reliable predictor of disease progression (Mellors *et al.* 1995). Other factors that may have an effect on longer-term progression at this stage include the appearance of HIV-1-specific CD8⁺ T cells, whose absence in macaques leads to an accelerated clinical course. Host genetic factors and, most significantly, being homozygous for a deletion in the chemokine coreceptor CCR5 can result in resistance to HIV-1 infection (Samson *et al.* 1996). Individuals expressing the HLA-B57 haplotype also show more controlled viral replication following acute infection (Altfeld *et al.* 2003).

Asymptomatic phase. This follows the acute illness and may last for many years, during which the person is nonetheless infective. Viral levels remain low in the blood, but high levels of activity are maintained in the lymphoid system. The semen, blood and possibly cervical secretions are particularly infective. There is no clear evidence of spread by saliva, ingestion or droplet inhalation, nor by casual or social contact. However, health-care workers must beware needle-stick injuries.

Generalised lymphadenopathy persists in up to one-third of patients after seroconversion, and minor skin complaints may be troublesome, including seborrhoeic dermatitis, but otherwise the person remains well. Thrombocytopenia of severe degree occasionally occurs. Throughout this period CD4 counts remain in the normal range (450–1500/ μ L in women; 350–1440/ μ L in men), but tend to decline slowly with time. The duration of the asymptomatic phase varies widely, most persons progressing to further stages within 2–10 years but some remaining well for considerably longer. Cohort studies of men who have sex with men have shown that up to half remain free from AIDS 10 years after initial infection and that 8% can remain clinically normal after 10–15 years (Buchbinder *et al.* 1994; Rutherford 1994). Moreover, some 5% appear to have non-progressive infection in that they do not show declining CD4 counts. Estimates of survival in a cohort of haemophilic men, based on extrapolations of changes in CD4 counts, suggest that as many as one-quarter may remain free from AIDS for 20 years (Phillips *et al.* 1994). HAART has had a significant impact on survival and particularly progression of the disease (Torres & Barr 1997) and is briefly reviewed later.

Early symptomatic infection. This begins to appear as the proportion of infected lymphocytes increases. Cell-mediated immunity falls, and recurrent viral infections such as herpes or warts make an appearance. Infections may also result from common bacterial pathogens such as pneumococcus, *Haemophilus* and *Salmonella*. Recurrent vaginal candidiasis may occur in women.

Late symptomatic infection. This includes a constellation of symptoms that predict progression to AIDS. Oral candidiasis and hairy leucoplakia of the tongue and cheek are usually of serious import. Constitutional symptoms include low-grade pyrexia, night sweats, weight loss, fatigue and diarrhoea. The most valuable laboratory marker of disease progression is the declining trend in CD4 count, which correlates with progression to AIDS and HIV RNA viral load. Serum markers reflecting immune activation (β_2 -microglobulin and neopterin) may yield additional information for assessing prognosis, but are less valuable. In developed countries, laboratory markers are the most reliable in terms of measuring disease progression and avoid the difficulties associated with identifying clinical signs (Mellors *et al.* 1997; Vlahov *et al.* 1998). Oral candidiasis, once seen as an excellent predictor of disease progression, may not be reliable enough unless the clinical history is also taken into account (Hilton 2000). In a cohort from New York, oral lesions were not predictive of progression in subjects with a CD4 count ≥ 200 / μ L (Begg *et al.* 1997). The value of oral lesions in predicting progression to AIDS needs further investigation in the developing world, where it may well be

more useful in the absence of access to laboratory investigations (Birnbaum *et al.* 2002).

AIDS-defining illnesses. These finally make their appearance as definitive indications of severely compromised immunological function. By this stage viral replication is increasing rapidly and the CD4 count has generally fallen below 200/ μ L. The three principal groups of illnesses are opportunistic infections, certain neoplastic conditions and the results of direct involvement of the nervous system by HIV. This last may antedate evidence of immunodeficiency.

In the untreated, opportunistic infections are legion, affecting the lungs, gastrointestinal tract and nervous system as low-grade organisms that have previously been tolerated gain hold. Pneumonia results from *Pneumocystis carinii*, cytomegalovirus (CMV), herpes simplex virus (HSV), *Cryptococcus* and atypical mycobacteria. Tuberculosis has increased substantially in HIV-infected patients in Africa where it is a common opportunistic problem (Lucas *et al.* 1993). Severe diarrhoea may be caused by the protozoan organisms *Cryptosporidium*, *Isospora belli* and microsporidia; also *Candida*, CMV and *Mycobacterium avium intracellulare*. The range of infections affecting the CNS is discussed in detail in Opportunistic infection of the CNS, later in chapter.

Neoplasias characteristically consist of Kaposi's sarcoma of the skin or other organs, lymphomas, or more rarely squamous carcinoma of the mouth or anorectum. Direct HIV infection of the nervous system is described in Primary HIV infection of the CNS, later in this chapter. Other conditions may mark the later stages of infection, including lymphoid interstitial pneumonitis, granulomatous hepatitis and recurrent salmonella septicaemia.

Petruckevitch *et al.* (1998) conducted a retrospective cohort study between 1982 and 1995 of 2048 HIV-infected individuals in London from different ethnic and racial backgrounds to identify disease progression and survival following specific AIDS-defining conditions. PCP accounted for one-quarter of AIDS presentations and tuberculosis for 16%. High-grade lymphoma carried the highest risk of death in HIV-infected individuals, whereas tuberculosis carried the lowest risk.

Classification of HIV-related illness

Historically, three categories of disorder were recognised following the asymptomatic stage: persistent generalised lymphadenopathy (PGL), AIDS-related complex (ARC) and acquired immunodeficiency syndrome (AIDS).

PGL is identified by enlargement of lymph nodes (1 cm or more in diameter) in at least two extrainguinal sites and persisting for at least 3 months. One-third of such cases show associated splenomegaly. PGL is largely symptomless, and is often thought to carry a relatively good prognosis with respect to early further progression. However, a proportion

of such patients show peripheral nerve disorder, and subjective memory difficulty and affective disorder appear to be commoner than in controls (Janssen *et al.* 1988). Neuropsychological evaluation may confirm mild cognitive impairment.

The definition of ARC is a category of chronic disease that fails to fulfill the criteria for AIDS in that there is no clear evidence of opportunistic infection or neoplasia. The diagnosis usually requires two or more of the following persisting for at least 3 months: low-grade pyrexia, weight loss exceeding 10% of body weight, PGL as defined above, oral candidiasis, diarrhoea, night sweats or fatigue interfering with work. One or more laboratory abnormalities such as decreased CD4 lymphocyte counts are sometimes required in addition.

The original diagnosis of AIDS came about only when there was reliable evidence of a disease at least moderately indicative of underlying cellular immune deficiency, for example Kaposi's sarcoma (in a person under 60) or some opportunistic infection. Other causes of cellular immune deficiency or of reduced resistance to infection had also to be excluded. In the era of antiretroviral therapy, effective prophylaxis against opportunistic infections and routine laboratory surveillance of CD4 and viral load, the case definition of AIDS has been somewhat revised. The most accepted classification system of HIV infection remains that revised by the Centers for Disease Control and Prevention (CDC) in 1993, after its initial publication in 1986. The system classifies individuals on the basis of CD4 count and three clinical categories, forming a matrix of nine mutually exclusive categories (Table 7.1).

The diagnosis of AIDS is confined to patients infected with HIV when they develop certain defined opportunistic infections or malignancies for the first time, for example PCP,

Kaposi's sarcoma or other specified conditions including HIV-related encephalopathy. In addition, the USA surveillance case definition of AIDS has been expanded to include HIV-positive persons whose CD4 lymphocyte count is less than 200/ μ L (or CD4 percentage <14%). As clearly seen in the matrix, categories A3, B3 and C1–C3 would fulfill the CDC definition of AIDS. An analogous classification system has been revised for HIV infection in children less than 13 years of age (Centers for Disease Control 1994).

The World Health Organization (WHO) published its clinical staging and case definition for HIV, particularly for use in resource-constrained settings, in 1990 and this was revised in 2005. The major difference between this system and the CDC system is that a CD4 count is not required, the focus being on clinical findings. The definition is divided into primary HIV infection and four clinical categories (World Health Organization 2005).

Neuropsychiatric manifestations

The HIV disease has proved to be of immense importance to neurology and psychiatry, not least in terms of the considerable economic burden that neuropsychiatric disorders add to treating patients with HIV (Yeung *et al.* 2006). Early reports by Snider *et al.* (1983) and Levy *et al.* (1985) drew attention to the range of neurological problems encountered and set the stage for their elaboration. It was also soon evident that the psychosocial consequences of infection could lead to profound emotional disturbance, even among those who were physically well or had sustained no more than a risk of exposure to the virus. Vulnerable persons, in groups at special risk, could display neurotic and sometimes psychotic symptomatology that needed to be distinguished from the effects of brain pathology. In this manner neurology and psychiatry have been drawn closer together in seeking to disentangle the impact of the disorder. In the sections that follow those disorders reflecting identifiable pathology are considered first, where possible comparing the pre- and post-HAART eras, then those that may be viewed as 'reactions' to knowledge of being infected. Estimates of the prevalence of neurological involvement in pre-HAART HIV-seropositive patients has been reported to be in the range 40–70% (Levy *et al.* 1985; Simpson & Berger 1996; Janssen 1997; Sacktor 2002). A similar prevalence rate is seen in developing countries where HAART may not be available (Grant *et al.* 1997; Satishchandra *et al.* 2000).

Special importance attaches to the resulting manifestations of CNS involvement in that they can be the presenting feature in some 10–20% of symptomatic HIV-1 infection (Levy *et al.* 1988). The nervous system is an early target in HIV disease (Resnick *et al.* 1988; Davis *et al.* 1992), with abnormalities developing in the CSF in a large proportion of asymptomatic HIV-positive individuals (Marshall *et al.*

Table 7.1 Case definition of AIDS as revised by the Centers for Disease Control and Prevention in 1993.

CD4 cell count	Clinical categories		
	A	B	C
$\geq 500/\mu\text{L}$	A1	B1	C1
200–499/ μL	A2	B2	C2
<200/ μL	A3	B3	C3

Category A (asymptomatic, acute HIV infection or PGL): transient symptoms at the time of or shortly after seroconversion or no symptoms or PGL, as defined above.

Category B (symptomatic conditions): for example oropharyngeal candidiasis, oral hairy leucoplakia or constitutional symptoms such as fever $>38.5^\circ\text{C}$ or diarrhoea lasting >1 month.

Category C (AIDS-indicator conditions): neurological conditions such as HIV encephalopathy, PML and cerebral toxoplasmosis.

1988). In a prospective study of homosexual men, McArthur *et al.* (1988) were able to demonstrate CSF abnormalities, and sometimes to isolate the virus from the fluid, within 6–24 months of seroconversion. Ho *et al.* (1985) detected the virus in the CSF of a patient suffering from aseptic meningitis at the actual time of seroconversion and Morris *et al.* (1998) identified a high HIV RNA viral load in the CSF from other patients with lymphocytic meningitis. There have also been reports of acute encephalopathy (Carne *et al.* 1985) and myelopathy (Denning *et al.* 1987) associated with primary HIV infection or at seroconversion. Post-mortem studies have revealed subtle polymerase chain reaction (PCR) positivity in the brains of some late symptomatic HIV-positive cases (Bell *et al.* 1993; Sinclair *et al.* 1994) and Davis *et al.* (1992) identified this finding in a case of iatrogenic HIV infection 15 days prior to death. There is, understandably, a scarcity of post-mortem studies of HIV-positive individuals who have died accidentally during the asymptomatic period. Of those that exist, they are predominantly from haemophiliacs who have died from other associations with their blood disorder or drug users who have died as a result of drug-related accidents (Gray *et al.* 1996; Esiri *et al.* 1989; Bell *et al.* 1993). The neurohistological features reported in these cases are of a predominantly CD8 lymphocytic infiltrate present in the leptomeninges and perivascular spaces of the central white matter. There is neuronal loss (An *et al.* 1996) and evidence of axonal injury is also suggested by the presence of β -amyloid precursor protein in some reports (An & Scaravilli 1997) together with microgliosis and astrogliosis. HIV DNA in the brain tissue of asymptomatic individuals has also been isolated and immune activation together with the presence of toxic cytokines has been reported.

By the time patients with AIDS, in the pretreatment era, had come to post-mortem, neuropathological changes were demonstrated in over 90% of cases, even in patients who had shown no relevant neurological symptomatology during life (Budka *et al.* 1987). Multiple pathologies were reported in about one-third of cases (Levy *et al.* 1988). The pictures observed were therefore pleomorphic and can still present considerable problems for diagnosis. Three main forms of involvement were recognised: opportunistic infections, neoplastic change and direct invasion of the nervous system by HIV. Indeed, before HAART, HIV encephalitis (HIVE) and opportunistic infections were reported in up to 50% of individuals with AIDS. A similar percentage of pretreatment cases of AIDS have been noted to show vacuolar myelopathy, myelin pallor and accumulation of macrophages in the spinal cord. Thus neurological involvement can span the entire spectrum of HIV infection, from the time of seroconversion to its most advanced manifestations. In 1991, Budka developed standard nomenclature for HIV neuropathology, which continues to be used. Additional pathology in the CNS results from vascular disorders, such

as vessel calcification, infarction, haemorrhage and vasculitis; such features have been noted where there is no evidence of opportunistic infection or HIVE, prior to the development of effective treatment strategies. The brain is also vulnerable to hypoxia and metabolic derangements due to pulmonary, hepatic and renal failure, and to the toxic effects of systemic infections or drugs, including HAART and other treatments used in the prophylaxis of opportunistic infection.

Since the introduction of HAART, there have been a number of cohort studies reporting a change in the prevalence of neuropathological manifestations of the virus, with data extending across pretreatment and treatment periods (Jellinger *et al.* 2000; Masliah *et al.* 2000; Sacktor *et al.* 2001; Morgello *et al.* 2002; Vago *et al.* 2002; Gray *et al.* 2003; Langford *et al.* 2003). While the prevalence of opportunistic infections is consistently reported as having declined, HIVE remains a more common finding than might be expected and there is the suggestion in some studies that a significant decrease in incidence has not been evident. Furthermore, Gray and colleagues have reported 'burnt-out' lesions of opportunistic infections and HIVE where neither inflammatory infiltrates nor the causal agent could be identified, representing variants of neuropathology in the context of HAART. Interest has also more recently focused on clinical deterioration after immune reconstitution as a result of HAART (Riedel *et al.* 2006).

A very approximate guide to the relative frequency of the different forms of pathology seen in the era before HAART is given by Petito *et al.*'s (1986) review of neuropathological findings in 153 patients dying from HIV disease; 28% showed evidence of HIVE, 26% encephalomyelitis due to CMV, 10% toxoplasmosis, 6% CNS lymphoma and 29% vacuomyelopathy of the cord. However, different risk groups of patients may be differently affected. Lantos *et al.* (1989) showed that haemophiliacs were less likely to develop HIVE while vascular lesions were common. Children are unlikely to develop opportunistic infections or lymphomas, but mainly show the picture of HIVE.

The frequency of CNS pathology before antiretroviral drugs (1984–1987) during monotherapy with zidovudine (1988–1994), dual therapy (1995–1996) and HAART (1997–2000) is reported by Vago *et al.*'s (2002) review of neuropathological findings in 1597 consecutive post-mortems of patients performed between 1984 and 2000; 76% were affected by opportunistic infections, HIV-related disease (encephalitis/leucoencephalopathy) or both. The prevalence of HIVE or leucoencephalopathy in each of the four periods was 54%, 32%, 18% and 15% respectively, a highly statistically significant reduction over time. Indeed, there are a number of excellent cohort studies of the neuropathology of HIV before and after HAART. On the whole these report general decreases in the prevalence of opportunistic infections, although HIVE would appear to be more common (Sacktor *et al.* 2002; Gray *et al.* 2003; Bell 2004).

Opportunistic infections of the CNS

Viral, fungal and parasitic infections of the CNS are common, while bacterial invasion is rare. The manifestations are broadly similar to those occurring in other settings except that they are more florid in the immunocompromised state. This may also be due in some instances to coinfection with HIV, which serves to exacerbate the tissue destruction.

Such infections occur in about one-third of untreated patients (De la Monte *et al.* 1987) and multiple infections are common (Gray *et al.* 1988). The incidence of the different organisms varies geographically (Everall & Lantos 1991). The principal infections encountered are toxoplasmosis and viral infection with CMV, HSV and varicella-zoster virus (VZV), also the polyomavirus leading to progressive multifocal leucoencephalopathy (PML). Fungal infections include *Cryptococcus*, *Candida albicans* or more rarely aspergillosis and coccidioidomycosis. The tubercle bacillus is occasionally involved, also other mycobacteria, *Escherichia coli*, *Listeria*, *Histoplasma* and *Treponema pallidum*. The detailed pictures are described by Levy *et al.* (1988) and the imaging appearances by Offiah and Turnbull (2006) and are presented here in summary form.

Toxoplasmosis. This is the result of reactivation of latent infection with the obligate intracellular protozoon *Toxoplasma gondii*. Primary infection is asymptomatic in 90% of immunocompetent individuals, although cervical or generalised lymphadenopathy has been seen in some. IgG antibodies to *T. gondii* are found in 20% of British and around 90% of French adults. These variations in immunocompetent prevalence are mirrored in HIV-seropositive cases. Toxoplasmosis appears to be especially frequent among patients from Haiti and Florida and also from France. The infection leads to an acute focal or diffuse meningoencephalitis, presenting usually with headache (45–65%), fever (10–75%) and altered consciousness, and focal neurological signs (50–60%) such as hemiparesis, aphasia or cerebellar ataxia. These may be preceded for several days or weeks by lethargy, confusion (40–50%) or weakness. Koppel *et al.* (1985) found that patients with focal neurological features usually proved to have toxoplasmosis and any neurological signs that may suggest CNS involvement should indicate neuroimaging, as toxoplasmosis is the most common and easily treated opportunistic infection in HIV-infected patients. Computed tomography (CT) or magnetic resonance imaging (MRI) reveal multiple ring or nodular, enhancing, isodense or hypodense white matter, corticomedullary or basal ganglia lesions (Fig. 7.1). Seizures occur in some 15% of cases. Raised intracranial pressure is rare.

The pathology consists of scattered focal areas of abscess formation, varying in size according to the patient's immunological response. Each has a necrotic core surrounded by granuloma formation consisting of an intense mononuclear

Fig. 7.1 Postcontrast MRI showing an enhancing ring lesion due to cerebral toxoplasmosis affecting the right superior cerebellar peduncle in an HIV-positive woman presenting with acute neurological and cognitive deterioration. (Courtesy of Dr John Moriarty.)

reaction. Encysted *T. gondii* and tachyzoites can usually be detected. Thrombosis of blood vessels may lead to large areas of necrosis, producing mass lesions in the brain. Early diagnosis can lead to a dramatic response to combination treatment with pyrimethamine and sulfadiazine (see Treatment of opportunistic infections, neoplasms and neuropsychiatric complications, later in chapter). Lumbar puncture often reveals a pleocytosis and elevation of protein. The incidence of toxoplasmosis has markedly decreased since the introduction of HAART (Gray *et al.* 2003; Anthony *et al.* 2005).

Cytomegalovirus. CMV is most common in patients with advanced infection and typically leads to subacute encephalitis with fever, memory and attention impairment, apathy, headache and ataxia. The pathology varies in severity from isolated cytomegalic cells to multiple necrotising lesions, the most common feature being diffuse, microglial, nodular encephalitis in the deep grey matter (Everall & Lantos 1991). The ventricular lining is frequently involved, likewise the choroid plexus. Microglia and macrophages contain intranuclear inclusions indicative of the presence of the virus. Clinical examination reveals cognitive impairment that can be similar to Korsakoff's psychosis with psychomotor retardation or dementia. MRI can be normal or reveal non-specific abnormalities with atrophy or ventricular enlargement in 40% (Clifford *et al.* 1996). Concurrent retinitis is common and is the most frequent cause of loss of vision in

AIDS. Treatment with ganciclovir and foscarnet has been found useful in CMV retinitis and encephalitis.

Herpes simplex. This produces a severe haemorrhagic encephalitis, typically limited to the temporofrontal regions (see Non-geographically restricted sporadic encephalitides, later), presenting with headache, fever, seizures, aphasia and other focal neurological deficits (Grover *et al.* 2004). Necrosis and softening affect both the grey and white matter, and eosinophilic nuclear inclusions are seen in neurones and glial cells. Occasional cases present as an ascending myelitis.

The VZV may involve the peripheral or central nervous system, the latter leading to diffuse encephalitis with multiple necrotic lesions similar to those of PML. Small eosinophilic inclusions in neurones and glial cells contain the virus.

Progressive multifocal leucoencephalopathy. PML results from infection with the JC polyomavirus. The virus is usually acquired in childhood and remains dormant. It has not been isolated in the brains of immunocompetent patients. It usually presents with the subacute development of mental impairment accompanied by varied neurological deficits. Dementia, blindness, dysphasia, hemiparesis and ataxia are among the classic features. CT may be normal or show characteristic low-density lesions in the white matter with a 'scalloped' appearance to their margins, without mass effect, enhancement or associated oedema. MRI may show that the grey matter is involved as well, possibly reflecting a more aggressive form of the disease in the presence of AIDS (Mark & Atlas 1989). The virus can be detected in the CSF by PCR in patients with and without PML.

The lesions consist essentially of areas of demyelination with sparing of axis cylinders and often with necrosis. Polyomavirus can be detected around the margins of the bizarre glial cells that are the hallmark of the disorder: enlarged astrocytes with distorted nuclei and oligodendrocytes containing eosinophilic inclusions. The condition carries a grave prognosis, with a median survival of 4 months (Fong & Toma 1995). Ante-mortem diagnosis can be made by biopsy. No treatment has proven efficacy, although anecdotal evidence suggests benefit from high-dose acyclovir, cytosine and adenosine arabinoside, interferons and steroids. Survival may be increased with HAART (Clifford 1998), although there has been no change in the incidence of PML since the introduction of HAART (Anthony *et al.* 2005).

Cryptococcus neoformans. This is the commonest fungal infection of the CNS, typically leading to a subacute granulomatous meningitis producing a gelatinous exudate at the base of the brain. Headache and malaise may be the sole complaints, perhaps because of the minimal inflammatory response. In other patients progressive headache, photophobia and nuchal rigidity are accompanied by confused and altered behaviour. Sometimes there is additional cyst and

granuloma formation within the brain, such patients presenting with focal neurological signs. Raised intracranial pressure may develop in consequence of hydrocephalus. The diagnosis is confirmed by lumbar puncture. Cells may be absent and the protein and glucose normal, but India ink staining reveals the fungus in a high proportion of cases. Detection of cryptococcal antigen in the CSF is a more reliable procedure. Treatment includes amphotericin B, flucytosine and fluconazole. Sacktor *et al.* (2001) identified that the incidence of *Cryptococcus* decreased in the Multicenter AIDS Cohort Study between 1990 and 1998, when antiretroviral treatments became available.

Candida albicans. This rarely involves the brain despite the frequency of this infection elsewhere in the body in HIV disease. When it does invade the CNS this takes the form of meningitis or multiple brain abscesses with focal neurological signs.

Coccidioidomycosis. This may produce a chronic relapsing meningitis, which is occasionally fulminant with microabscess formation in the brain.

Tuberculous infection. This can present either with a mass lesion or as tuberculous meningitis (described under Tuberculous meningitis, later).

Treponema pallidum. This may lead to neurosyphilis after an unusually brief latent interval, and sometimes despite previous adequate therapy for the initial syphilitic infection (Nieman 1991). In the immunocompromised state the manifestations of meningovascular syphilis may be especially florid, leading to unusual acute neurological syndromes, although there is controversy as to whether coinfection does result in more aggressive syphilis. Serological tests for syphilis may also be altered, becoming positive in the CSF only after repeated serial testing (Lynn & Lightman 2004). Further discussion of HIV and syphilis coinfection can be found under Neurosyphilis and HIV coinfection, later.

Neoplasia of the CNS

The commonest CNS neoplasm is a primary non-Hodgkin's malignant lymphoma; in the pre-HAART era this occurred in some 4–7% of patients with neurological complaints. Some studies suggest that the prevalence of non-Hodgkin's lymphoma has not decreased to the same extent as other sequelae of AIDS, despite antiretroviral therapy (Grulich 1999; Conti *et al.* 2000).

This is a B-cell lymphoma, unifocal in 33–50% of cases (Ciacci *et al.* 1999) but sometimes multifocal and extensive, involving the cerebral hemispheres, cerebellum and brainstem. The presentation is usually with focal neurological deficits, similar to those seen with toxoplasmosis or PML, but with more gradual onset (Stern & Marder 1991). Sometimes,

however, the picture can be surprisingly non-specific with lethargy, confusion and memory impairment (Rosenblum *et al.* 1988) in as many as 60% of cases. Headache and evidence of raised intracranial pressure may be lacking and unexplained fever may occur. Seizures develop in 15–44% of cases (Chamberlain & Kormanik 1999).

The pictures on brain imaging may also be hard to distinguish from toxoplasmosis or PML. The space-occupying lesions show ill-defined margins with surrounding oedema, and may enhance irregularly (Sze *et al.* 1987). They lie mainly in the basal ganglia, thalamus, corpus callosum and cerebellum and, occasionally, brainstem. Analysis of CSF for Epstein–Barr virus (EBV) using PCR has high sensitivity and positive and negative predictive value (Cinque *et al.* 1996) and is now the investigation of choice. Biopsy may be needed for definitive diagnosis, or the distinction may ultimately be made by the rapid initial response to radiation. The long-term effects of treatment are poor, with a median length of survival of 1–3 months, even with whole-brain irradiation. Limited evidence suggests that there may be some benefit on survival for those receiving protease inhibitors as well as chemotherapy for lymphoma (Jacomet *et al.* 1997).

Pathological examination shows lymphoid cells invading vascular walls and brain tissue, along with a marked astrocytic response. EBV is found in lymphoma cells in nearly 100% of cases and may be identified by *in situ* hybridisation (Hamilton-Dutoit *et al.* 1991). Secondary brain involvement from lymphoma elsewhere in the body occurs more rarely, also metastatic deposits from Kaposi's sarcoma. Plasmocytomas and lymphoid granulomatosis may also occur.

Primary HIV infection of the CNS

As described above, it has become clear that the nervous system is a prime target for HIV in addition to its predilection

for the immune system. This was not at first apparent, but has now been fully proven by electron microscopy, immunocytochemistry and *in situ* hybridisation and PCR. Shaw *et al.* (1985) were the first to identify the virus in 5 of 15 brains from AIDS patients with dementia, and Koenig *et al.* (1986) showed that the cell type harbouring the virus was the macrophage and the multinucleated giant cells deriving from it (Figs 7.2 and 7.3: see also Plates 7.1 and 7.2). Such cells often contain enormous quantities of the virus. The microglia are also involved and, like macrophages, are the only cells in the CNS to possess both CD4 and chemokine receptors. Oligodendrocytes and vascular endothelial cells may be infected, as well as astrocytes (Saito *et al.* 1994) and neurones (Torres-Munoz *et al.* 2001). The mechanism whereby HIV attaches to astrocytes and neurones, neither of which have CD4 receptors, is not clear and while the virus has been detected in some studies, the findings are not consistent. The evidence for HIV infection of cells in the CNS is summarised by Bell (2004). As has been discussed, evidence has accumulated to suggest that the nervous system is infected at an early stage of the disease, even though pronounced clinical sequelae may take a considerable time to appear.

The 'Trojan horse' hypothesis proposes that activated CD14⁺/CD16⁺ or HIV-infected monocytes carry the virus through the blood–brain barrier (Fischer-Smith *et al.* 2004). There is also evidence that activated T lymphocytes can enter the CNS. Alternatively, the virus may enter and replicate in the vascular endothelium, or via the choroid plexus and CSF. Entrance by way of peripheral nerves has also been considered.

The consequences of such invasion have been clarified to some extent at the level of tissue pathology, with the delineation of several more or less distinct patterns of neuropathogenesis. However, their clinical counterparts are as yet unclear, and classification in terms of presenting clinical

Fig. 7.2 Large multinucleated giant cells in cerebral white matter of a patient with HIV encephalitis and dementia (see also Plate 7.1). Haematoxylin and eosin, magnification $\times 250$. (Courtesy of Dr Ian Everall.)

features remains sometimes confusing in its historical nomenclature. The major clinical syndromes that appear to be due to primary brain infection are the so-called 'HIV-associated dementia' and 'HIV-associated minor cognitive and motor disorder' that had previously been called 'AIDS-dementia complex' as well as the progressive encephalopathy that occurs in children. Aseptic meningitis is almost certainly so caused. Vacuolar myelopathy of the spinal cord, distal sensory polyneuropathy (DSPN) and HIV polymyositis are also seen.

The clinical uncertainties are due to a lack of long-term prospective studies from which clinicopathological correlations may be drawn, also to the coincident operation of opportunistic infections and other pathologies in many pre-treatment cases and the effects of immune reconstitution in those receiving HAART (Landay *et al.* 2002). The pathological changes associated with HIV infection are therefore briefly reviewed before consideration of the clinical pictures encountered.

HIV-associated pathology of the CNS

Budka *et al.* (1991) have produced a consensus report for the classification of HIV-associated neuropathologies as listed below. Everall and Lantos (1991) provide a concise description of the several categories. By far the most common are HIVE, HIV leucoencephalopathy and vacuolar myelopathy. With some pathologies, namely HIVE and HIV leucoencephalopathy, there is clear evidence that the lesion is caused by HIV itself, these forms not occurring in other settings of immunosuppression. In the others, the pathogenic role of direct HIV infection is less completely established.

HIV encephalitis. This term refers to the picture of multiple foci of inflammatory change throughout the cortex and white

matter, also involving the basal ganglia and brainstem. The neocortex may be spared relative to deeper parts of the brain, and the globus pallidus is often particularly severely affected. The foci consist of aggregations of macrophages, microglia and multinucleated giant cells (Bell 1998), these last being the hallmark of the condition and probably deriving from macrophages (see Figs 7.2 and 7.3; see also Plates 7.1 and 7.2). The glycoprotein gp41 on the surface of HIV mediates cell fusion and may be responsible for the formation of these characteristic cell syncytia. HIV can be detected in all three types of cell. In addition, there may be foci of microglial nodules in white and grey matter together with damage to myelinated fibres. Myelin damage ranges from pallor to breakdown and loss, often with axonal injury, the latter being confirmed by the presence of β -amyloid precursor protein in the white matter varicosities and axon bulbs.

HIV leucoencephalopathy. This is the term given to such cases of HIVE with significant white matter injury. It is characterised by diffuse and usually symmetrical white matter damage, particularly in deep areas of the centrum semiovale, involving loss of myelin, reactive astrocytosis and the accumulation of macrophages and multinucleated giant cells. Such indications of inflammatory change are accompanied by alterations in small blood vessel walls and possible damage to the blood-brain barrier. A degree of overlap with HIVE is sometimes obvious and the validity of the distinction between the two is not firmly established. It is possible that they represent the same pathological process, but with accent on the white matter in HIV leucoencephalopathy.

It must be distinguished from the so-called 'myelin pallor' frequently observed in the deep white matter with myelin stains. This is an extremely common finding in patients with HIV disease and may be the sole brain abnormality at post-mortem. The myelin sheaths are preserved, and the

appearances may be mainly due to increased interstitial water or represent an artefact of staining techniques.

Vacuolar myelopathy is a distinctive finding confined to the spinal cord, chiefly in the cervical and high thoracic regions and mainly affecting the dorsal and lateral white matter tracts. It is often a late development. Multiple areas show vacuolar myelin swellings, similar to the lesions seen in subacute combined degeneration due to vitamin B₁₂ deficiency. Decreased CSF S-adenosylmethionine concentrations suggest that abnormal B₁₂-dependent transmethylation may be an important part of pathogenesis (Di Rocco *et al.* 2002). The early lesions show scattered vacuoles due to swellings within the myelin sheaths and occasional lipid-laden macrophages; with severe cases there is secondary axonal degeneration (Petito *et al.* 1985; Petito 1988; Shepherd *et al.* 1999).

Virological studies have not implicated HIV conclusively, with pathological evidence of active HIV infection being found in only 6% of cases (Petito *et al.* 1994). The virus can be cultured from the cord, but has not been demonstrated in the areas with vacuolar change. Other viruses could be responsible, or nutritional and metabolic factors could play a part.

Vacuolar leucoencephalopathy shows a not dissimilar picture affecting the white matter of the cerebral hemispheres, cerebellum, basal ganglia and brainstem. It may accompany HIV leucoencephalopathy.

Distal sensory polyneuropathy is characterised by the infiltration of lymphocytes and activated macrophages, decreased numbers of neurones and high numbers of nodules of Nageotte in the dorsal root ganglion. HIV infection of the dorsal root ganglion has been shown by PCR hybridisation *in situ* (Brannagan *et al.* 1997) but there is more evidence for the virus to be harboured in the nodules of Nageotte and perivascular inflammatory cells (Yoshioka *et al.* 1994).

Diffuse poliodystrophy consists of diffuse astrocytosis, gliosis and microglial activation in the grey matter of the cerebral cortex, basal ganglia and brainstem nuclei. This is the only category in Budka *et al.*'s (1991) classification that recognises the possibility of the neuronal loss (discussed below). The validity of diffuse poliodystrophy as a separate entity is uncertain, since gliosis is so commonly found in patients dying from HIV disease.

Cerebral vasculitis including granulomatous angiitis consists of infiltration of the walls of cerebral blood vessels with lymphocytes and multinucleated giant cells. There may be accompanying areas of necrosis.

Lymphocytic meningitis usually occurs soon after HIV infection as a self-limiting condition, but may recur or appear for the first time later in the asymptomatic or early symptomatic phases. The usual pathogens responsible for meningitis cannot be isolated, but in many cases HIV can be identified in the CSF.

Neuronal loss and cerebral atrophy with HIV infection

An important development has been the demonstration of substantial neuronal loss in the cerebral cortex of patients with HIV disease. Indeed, this is a common finding and somewhat surprising when it is considered that neurones are rarely infected by HIV (Torres-Munoz *et al.* 2001).

Everall *et al.* (1991) made counts in the frontal cortex of 11 patients with HIV disease, all without opportunistic brain infection or neoplastic change, and demonstrated a 38% depletion of neurones. Such loss was equivalently severe in the five with obvious HIVE and the six who showed only minimal pathology by way of slight astrocytosis and perivascular accumulations of mononuclear cells. Neuronal loss has since been established more widely in the occipital, parietal and superior temporal areas (Wiley *et al.* 1991; Everall *et al.* 1993a), also in the substantia nigra, putamen and cerebellar nuclei (Reyes *et al.* 1991; Abe *et al.* 1993; Everall *et al.* 1993b). However, the frontal losses have emerged as the most severe. A significant association has been observed between such losses and the presence of dementia in some studies (Achim *et al.* 1994; Wiley & Achim 1994; Asare *et al.* 1995). It is unclear as to whether cerebral atrophy is a marker of HIV dementia or of HIV infection alone (Subbiah *et al.* 1996). The presence of particularly subcortical atrophy and white matter changes on neuroimaging is remarkable in HIV-seropositive patients even in the absence of clinical deficits and has been found to be especially marked in the caudate for example on MRI (Dal Pan *et al.* 1992). Radiological changes are not necessarily associated with dementia scores.

The mechanisms responsible for HIV-associated neuronal death are unclear. It seems that the presence of HIVE with multinucleated giant cells is not an accurate marker for neuronal loss, which can occur in the presence of minimal or absent inflammatory change (Everall *et al.* 1993b). Thus dual pathogenic processes may be at work. Since neurones are only very rarely infected directly by HIV, one must postulate some 'toxic' effect on neuronal viability and it has been suggested that neuronal injury may occur through direct or indirect mechanisms. There is evidence for neuronal damage by numerous HIV proteins including env, Tat, Vpr and gp120. In studies of serum-free primary neuronal and neuroblastoma cell lines, where the confounding impact of excitatory amino acids and cytokines are absent, envelope proteins have been shown to be directly toxic. Blocking chemokine receptor signalling has been shown to prevent neuronal apoptosis induced by HIV gp120, suggesting that the envelope glycoprotein interactions with these receptors may mediate injury. gp120 has also been shown to interact with the glycine-binding site of N-methyl-D-aspartate (NMDA) receptors, providing another mechanism. Indirectly, it is hypothesised that effects on the NMDA receptor by phagocytic inflammatory mediators results in excessive intracellular calcium and the activation of a complex apoptotic cascade that includes initiation of caspases, free radical formation, lipid peroxidation and chromatin condensation. Apoptotic neurones have been isolated in HIV-seropositive patients by the identification of terminal deoxynucleotidyl transferase biotin-dUTP nick end labelling (TUNEL)-positive cells, DNA laddering and electron microscopic changes *post mortem*. Both microglial activation and axonal damage correlate with apoptosis, supporting the indirect inflammatory-mediated injury hypothesis (Adle-Biassette *et al.* 1999).

Dendritic morphology is also altered in the HIV-infected brain, with shortened, vacuolated and tortuous dendrites and a marked decrease in the number of dendritic spines (Wiley *et al.* 1994; Masliah *et al.* 1997). Synaptic density is reduced in the frontal cortex. These observations

have been made in brains with concurrent evidence of HIVE, so they, at least, may be a product of the inflammatory process.

HIV-associated cognitive disorders

There is a wide range of cognitive impairment reported in the literature, with a bewildering nomenclature. Generally, three categories are acknowledged at present: HIV-associated dementia (HAD), minor cognitive-motor disorder (MCMD) and neuropsychological impairment. Delirium is also recognised.

HIV-associated dementia (also called AIDS-dementia complex, HIV-related encephalopathy, AIDS encephalopathy, HIV-associated cognitive/motor complex, HIV encephalitis, subacute encephalitis)

Clinical pictures of CNS impairment occur against the pathological backgrounds described above and take a variety of forms. Prominent among them is a syndrome of progressive cognitive impairment, referred to by the bewildering variety of labels listed above, and generally carrying a poor prognosis. HIV-1 infection is recognised as the most common, preventable and treatable cause of cognitive impairment in those aged under 50. Evidence increasingly suggests that cognitive impairment results in large part from direct brain invasion by HIV, but beyond that it has continued to prove complicated to relate to defined aspects of brain pathology.

Terminology and definition

In early descriptions the condition was labelled 'subacute encephalitis' and thought to be due to opportunistic brain infection, probably with CMV (Snider *et al.* 1983; Levy *et al.* 1985). It was rechristened 'AIDS-dementia complex' by Navia *et al.* (1986a,b), 'complex' being added because motor and behavioural components were often prominent in addition to the cognitive failure. This latter term has since been abandoned, as patients presenting with dementia may not have AIDS-defining illness. The Working Group of the American Academy of Neurology (1991) proposed the terms 'HIV-1-associated minor cognitive-motor complex' and 'HIV-associated dementia' to designate the minor and major forms of cognitive impairment in HIV infection, the former not involving impairment in activities of daily living.

Diagnostic criteria have been recommended by the WHO Consultation Committee (World Health Organization 1990a) and, more recently, by the Working Group of the American Academy of Neurology AIDS Task Force, both of which are essentially modifications of the ICD-10 research criteria for dementia generally (Box 7.1) (see Chapter 9). These firm definitions have allowed for a refinement of the understanding of these disorders and aid their demarcation from other clinical syndromes. Such definitions will hopefully avoid what Catalan (1991) identifies, in many surveys of HIV-positive patients, that dementia has been used as an umbrella term,

Box 7.1 Diagnostic criteria for cognitive impairment in HIV infection

- I Acquired abnormality in at least two of the following cognitive abilities, present for at least 1 month and causing impairment in work or activities of daily living:
 - (a) Attention or concentration
 - (b) Speed of information processing
 - (c) Abstraction or reasoning
 - (d) Visuospatial skills
 - (e) Memory or learning
 - (f) Speech or language
- II At least one of the following:
 - (a) Acquired abnormality in motor functioning
 - (b) Decline in motivation or emotional control or change in social behaviour
- III Absence of clouding of consciousness during a period long enough to establish presence of I, above
- IV Absence of another cause of the above cognitive, motor or behavioural symptoms or signs (active CNS opportunistic infection or malignancy, psychiatric disorders, substance abuse)

encompassing syndromes of cognitive decline, sometimes without impairment of memory, also acute brain syndromes, motor syndromes and possibly conditions characterised chiefly by depression and other psychiatric disorders.

Epidemiology

The commonest CNS manifestation in patients with HIV disease has emerged as HIV-associated dementia. Before the development of antiretrovirals, Brew *et al.* (1988) reported that over 60% of patients dying of HIV disease in New York exhibited some degree of dementia prior to death. Catalan (1991) has reviewed various estimates of its prevalence, identifying a range from 8% to almost 40%, much probably depending on matters of patient selection and the criteria adopted for diagnosis. Prospective surveys in the UK have shown prevalence rates of 7–16% when other causes of chronic organic reactions, such as opportunistic infections, have been excluded. Grant *et al.* (2005) summarise the estimated prevalence of HAD at different stages of HIV infection: 1% in the asymptomatic phase, 3% at initial AIDS condition, 5–10% with symptomatic HIV disease and 10–20% with advanced disease. Treatment with zidovudine monotherapy was associated with a decrease in the incidence of HAD (Portegies *et al.* 1989; Chiesi *et al.* 1990; Catalan & Thornton 1993) and a decline in prevalence was initially suggested with the use of HAART, to as low as 10% in some cohorts. Nonetheless, it has been suggested in some studies that the initial improvements in prevalence figures have not

been sustained. The prolongation of survival times with effective treatments obviously plays a significant role in this (Graham *et al.* 1996). Furthermore, the poor penetration into the CNS by most antiretrovirals has also been proposed as an explanation (Maschke *et al.* 2000; Clifford 2002). McArthur (2004) reports that the prevalence of HAD and MCMD remain very high at 37% in one large North American cohort and that this is not significantly different from the pre-HAART comparison group. Further exploration of the changes in both incidence and prevalence is required.

Day *et al.* (1992) identified an annual incidence of HAD in symptomatic patients of 14% and McArthur *et al.* (1993) an annual rate of 7.1%. In intravenous drug users in Edinburgh, an incidence of 9% has been reported. This study also delineated the mean time from seroconversion to HAD as 9 years (Goodwin *et al.* 1996). The decreased incidence already noted with monotherapy, unlike prevalence rates, has been largely borne out with combination antiretroviral treatment, although some groups have continued to identify increases. In the Multicenter AIDS Cohort Study for example, the incidence of HAD has dropped by 50% since the introduction of HAART (Sacktor *et al.* 2001). In the pretreatment era, HAD was associated with CD4 counts of less than 200/ μ L in 70% of cases. In contrast with this, in the Multicenter AIDS Cohort Study during the period when HAART became widely available (1996–1998), there was an equal distribution of cases across the range of CD4 counts and therefore more cases presenting with counts in excess of 200/ μ L. Similar incidence and CD4 count findings have been replicated in Europe (Brodt *et al.* 1997; Mocroft *et al.* 2000), Australia (Dore *et al.* 1999) and in intravenous drug users in Baltimore (Moore & Chaisson 1999).

Risk factors

A number of factors have been investigated that have an association with, or are predictive of, development of HIV-associated dementia. In the pre-HAART era, the Multicenter AIDS Cohort Study data allowed for the estimation of predictors for HAD by a proportional hazards survival regression model. These included lower haemoglobin and body mass index up to 6 months before AIDS, more constitutional symptoms 7–12 months before and older age at transition to AIDS (McArthur *et al.* 1993). Similarly, Wang *et al.* (1995) identified an association with increasing age, but also injection drug use. The association with drug use has been replicated in several studies (Bouwman *et al.* 1998; Maschke *et al.* 2000; Becker *et al.* 2004) and Zhang *et al.* (1998) have reported that cocaine can affect HIV entry through the blood–brain barrier, which may explain this apparent association.

Plasma viral load and CD4 cell count have been identified as positive predictors of HAD (Childs *et al.* 1999). In the Multicenter AIDS Cohort Study, an HIV RNA count in excess of 30 000 copies/mL inferred a hazard 9.1 times that of a count below 500 copies/mL; similarly, a CD4 count below

200/ μ L predicted a 3.4-fold increased risk compared with a CD4 count in excess of 500/ μ L (McArthur *et al.* 1993). While demographic factors were not reliable predictors of dementia in the Multicenter AIDS Cohort Study, female sex (Chiesi *et al.* 1996) and low educational level (De Ronchi *et al.* 2002) have been suggested as possible associations. Several studies have proposed neuropsychological risk factors, most prominent being psychomotor slowing (Sacktor *et al.* 1996). Stern *et al.* (2001) further identified abnormal scores on measures of psychomotor and executive function as well as a diagnosis of minor cognitive–motor disorder, extrapyramidal signs and systemic HIV symptoms as significantly associated. Interestingly, this study also found a strong association with depressive disorder and later developing HAD that has been supported elsewhere.

In the era of HAART, serum viral load and CD4 count are perhaps less useful factors in identifying risk of HAD. Interest has turned to CSF markers, with Ellis *et al.* (1997) showing that CSF viral load and Letendre *et al.* (1999) that CSF chemokine concentration are associated with cognitive impairment. It would appear that HAART-related improvements in cognition are associated with improvements of these CSF markers in some studies, although Cysique *et al.* (2005) advocate caution when interpreting inactive CSF markers, as they are not necessarily indicative of inactivity of cognitive impairment. Positive associations between plasma tumour necrosis factor (TNF)- α and CSF macrophage chemoattractant protein (MCP)-1 levels and developing HAD have been proposed (Sevigny *et al.* 2004).

Further investigation of the genetic susceptibility to HAD is required. Corder *et al.*'s (1998) small study was the first to investigate this intriguing hypothesis, in which an association was found between the apolipoprotein E (APOE) $\epsilon 4$ allele and excess dementia.

Clinical features

The principal features of HIV-associated dementia are of disabling cognitive impairment, accompanied by behavioural change and often motor deficits (Snider *et al.* 1983; Levy *et al.* 1985). Behavioural manifestations include lethargy, social withdrawal, loss of spontaneity and also marked psychomotor slowing, which could at first be mistaken for depression. A confusional state can mark the outset and malaise is frequently profound.

Navia *et al.* (1986a,b) gave the first full description of the syndrome and its pathological background. They found it in 38% of 121 patients coming to post-mortem, or almost two-thirds in the absence of opportunistic brain infection or neoplasia. In one-quarter it appeared to antedate other manifestations of AIDS. Indeed, some cases failed to show systemic features of AIDS right up to the time of death (Navia & Price 1987). However, further experience has indicated that this is rare. The onset was sometimes insidious and sometimes fairly abrupt in Navia *et al.*'s cases. Impairment of

memory and loss of concentration were the commonest early symptoms. Mental slowing was prominent, and confusion often present. Approximately half presented with cognitive change, while in the remainder motor or behavioural changes predominated.

Motor dysfunction took the form of imbalance, ataxia or leg weakness, sometimes for several months before cognitive deficits appeared. Loss of fine hand coordination and deterioration of handwriting was frequently observed, together with clumsiness and tremor. Of the behavioural changes, apathy and social withdrawal were most frequent, irritability and emotional lability less so. Such changes were the opening feature in almost one-quarter of patients. The typical picture was of becoming subdued, with loss of interest and loss of emotional responsiveness.

Less common symptoms included headache, seizures and episodes of speech disturbance. Some patients showed psychotic episodes with delusions and hallucinations. Perry and Jacobsen (1986) described several patients who presented with acute psychoses resembling schizophrenia, acute paranoid disorder, mania or psychotic depression.

This clinical picture has been broadly confirmed in subsequent reports. On examination there may be little to find neurologically in the early stages, although rapid eye and limb movements may be impaired along with diffuse hyperreflexia. Later there is often ataxia of gait, leg weakness and clonus. Frontal release signs may be prominent, especially the snout reflex. Some patients show tremors and dysarthria, and evidence of peripheral neuropathy is common.

Course

The course is typically steadily progressive though punctuated at times by abrupt accelerations. Half of Navia *et al.*'s patients progressed to severe global impairment within 2 months, but some 20% followed a more protracted course. McArthur (1987) found that of 20 patients seen initially in the early stages, nine progressed to advanced dementia within a few months, while six remained stable and failed to deteriorate over 3–13 months. Once severely demented the mean survival time was less than 3 months. In 18 patients who died with dementia, the average interval from the first symptom of cognitive dysfunction to death was 5.5 months. McArthur *et al.* (1993) further reported a similar median survival of 6 months after diagnosis in the Multicenter AIDS Cohort Study. As has already been discussed, HAART has changed the course of this disorder. However, Sevigny *et al.* (2007) have recently reported that HAD remains a significant risk factor for death despite HAART and suggest that this may be associated with poor treatment adherence in the demented group.

Insight is often relatively preserved until late in the disorder. The delayed appearance of focal cognitive symptoms such as apraxia or agnosia is in keeping with the predominantly subcortical nature of the dementia. The final stages

are marked by severe global dementia, akinetic mutism, incontinence, paraplegia and sometimes myoclonus. Even in the terminal stages, however, the level of consciousness is unimpaired.

Investigations

Electroencephalography (EEG) is often normal initially, with diffuse slowing later. Neuroimaging usually shows variable cortical atrophy and ventricular dilatation, but the absence of atrophy does not countermand the diagnosis. White matter rarefaction is common, and MRI may show areas of increased T2 signal in the white matter that becomes more diffuse as the dementia progresses (Levy *et al.* 1986; Olsen *et al.* 1988). However, the essential role of neuroimaging is to exclude features indicative of treatable conditions such as opportunistic infections or lymphomas. Numerous neuroimaging studies reported during the course of HIV infection have been summarised by Tucker *et al.* (2004). In brief, positron emission tomography (PET) has demonstrated subcortical hypermetabolism in the thalamus and basal ganglia in the early stages, with progression to cortical and subcortical hypometabolism later (Rottenberg *et al.* 1987; von Giesen *et al.* 2000). Single-photon emission computed tomography (SPECT) may show perfusion deficits despite the absence of gross brain lesions (Costa *et al.* 1988). Maini *et al.* (1990) found that frontoparietal hypoperfusion correlated with HAD severity and Sacktor *et al.* (1995a,b) identified that perfusion abnormalities could be correlated with severity of cognitive deficit but particularly motor functioning in HAD. Volumetric MRI has substantiated the association between volume loss in specific structures and declining cognition. Magnetic resonance spectroscopy (MRS) has shown reduced levels of N-acetylaspartate indicative of neuronal loss, even in areas apparently normal on structural scans (Menon *et al.* 1990). More recent MRS studies have supported this finding and additionally revealed increases in glial markers, myoinositol and choline/creatinine ratios with progressing dementia (Paley *et al.* 1996; Yiannoutsos *et al.* 2000). Functional MRI studies have shown reduced activation in motor paradigms in HAD and MCMD as well as differences between patients and controls in working memory tasks (Tucker *et al.* 2004). Diffusion tensor imaging has revealed diffuse white matter disease across the spectrum of HIV-associated cognitive impairment (Hall *et al.* 2004).

Examination of the CSF is essential to exclude opportunistic infections. It may be normal, but elevation of protein and a mild lymphocytic pleocytosis can occur. However, this is non-specific and can be found in asymptomatic persons. Oligoclonal bands are sometimes detected and HIV may be isolated from the fluid. Levels of β_2 -microglobulin appear to correlate with the severity of the dementia (Brew *et al.* 1992) and reports have consistently suggested similar claims for neopterin, quinolinic acid and MCP (Perelson *et al.* 1997; Martin *et al.* 1998). The latter may be a predictive marker of

HAD when considered as a ratio of its serum concentration (Kelder *et al.* 1998). Unfortunately, as all these CSF markers are non-specific, they have not entered mainstream clinical use in the diagnosis of HAD. HIV RNA or viral load in the CSF has proven to be less clinically useful than was originally hoped (McArthur & Letendre 2006).

Differential diagnosis

The diagnosis of HIV-associated dementia during life is essentially one of exclusion. In mild examples differentiation will be required from anxiety or depression, also from fatigue and the effects of systemic illness. Metabolic causes of encephalopathy should be excluded, also the toxic effects of CNS-active medication, whether prescribed or abused, to which AIDS patients may be sensitive. When psychotic features are present it is important to consider the possibility of an independent schizophrenia or paranoid state.

With more severe dementia the essential differentiation is from opportunistic brain infections or neoplasia. Infections such as CMV, toxoplasmosis, neurosyphilis and cryptococcal or tuberculous meningitis must be carefully excluded since they lead to therapeutic options. Distinguishing features characteristic of CMV encephalitis include coexisting retinitis or colitis, electrolyte abnormalities reflecting adrenalitis, or periventricular abnormalities on MRI indicative of periventriculitis (McArthur *et al.* 1994). Other causes of dementia must clearly be considered, particularly in the middle aged or elderly.

Pathology

The pathological substrate of HIV-associated dementia remains unclear. Price (1994), and more recently in a historical review Scaravilli *et al.* (2007), summarise the attempts made to relate the severity of cognitive impairment to the extent and nature of brain pathology, but such correlations have proved far from exact.

At first it was identified that severe dementia was often associated with the prominent development of multinucleated HIV, while mild forms tended to show little more than white matter pallor and gliosis (Wiley & Achim 1994). On the whole, this correlation has not been replicated in the majority of cohorts (Navia *et al.* 1986b; Gray *et al.* 1991; Brew *et al.* 1995; Adle-Biasette *et al.* 1999). The suggestion that cortical neuronal loss may be a clinicopathological correlate, a plausible hypothesis in view of it being consistently reported in association with HIV, has not been supported (Giometto *et al.* 1997). Attempts to identify localised changes have revealed a range of different areas affected, including cell loss in the putamen (Everall *et al.* 1995), preferential frontal productive infection (Bell *et al.* 1998) and reactive hippocampal gliosis (Petito *et al.* 2001). Associations between dementia and leucoencephalopathy (Glass *et al.* 1993; Adle-Biasette *et al.* 1999) or poliodystrophy (Glass *et al.* 1993; Weis *et al.* 1993) have not been substantiated. A promising association

between dementia and microglial activation has been reported on a number of occasions, although this is a non-specific finding reported in other clinical scenarios. Successive stages of severity of dementia tend to arise in the context of increasing levels of systemic immunosuppression, raising the possibility that the virus both creates the opportunity for infection and then exploits it by infecting the CNS (Price 1994). However, there is much variability here as well, some patients failing to develop dementia despite repeated episodes of systemic opportunistic infection, while occasional patients develop severe dementia as the sole feature of the illness.

In an attempt to bring together the conflicting neuropathological picture, Scaravilli *et al.* (2007) propose a 'combined effects' model in the pathogenesis of HIV-associated dementia that allows for the range of conflicting evidence. They propose the concept that HAD results from the combined effects of HIV protein, glial and microglial activation mediated through oxidative stress and glutamatergic excitotoxicity.

Minor cognitive-motor disorder and neuropsychological impairment

The epidemiology of milder cognitive disorders has not been described as fully as for HAD, largely as a result of the reliability and acceptance of criteria and definitions for diagnosis. The definition of HIV-associated MCMD as proposed by the American Academy of Neurology AIDS Taskforce (1991) is shown in Box 7.2. It has been estimated

Box 7.2 Criteria for minor cognitive-motor disorder and neuropsychological impairment in HIV infection

- I Acquired cognitive, motor or behavioural abnormalities (must have both A and B)
 - A At least two of the following symptoms present for at least 1 month, verified by a reliable history:
 - (1) Impaired attention or concentration
 - (2) Mental slowing
 - (3) Impaired memory
 - (4) Slowed movements
 - (5) Incoordination
 - (6) Personality change, or irritability or emotional lability
 - B Acquired cognitive or motor abnormality, verified by clinical neurological examination or neuropsychological testing
- II Cognitive, motor or behavioural abnormalities causing mild impairment of work or activities of daily living (objectively verifiable or by report of key informant)
- III Does not meet criteria for HIV-associated dementia
- IV Absence of another cause of the above cognitive, motor or behavioural abnormalities (e.g. active CNS opportunistic infection or malignancy, psychiatric disorders, substance abuse)

that the prevalence is in the region of 5% in asymptomatic seropositive individuals and 18% during the symptomatic stage (Grant *et al.* 2005), although others have identified a much higher estimate of overall prevalence of 50–60%, even when treated with HAART (Sacktor *et al.* 2002). There is some suggestion that women may be at a higher risk of HIV-associated cognitive impairment (Janssen *et al.* 1992; Wojna *et al.* 2004). The transition from neuropsychological impairment to MCMD has not been clearly evaluated. Neuropsychological deficits in asymptomatic presentations are discussed in more detail under Impairment in asymptomatic HIV-positive subjects, later.

Vacuolar myelopathy of the spinal cord

Vacuolar myelopathy has been estimated to affect up to 55% of patients (Artigas *et al.* 1990) in advanced HIV infection and commonly in the context of HIV-associated dementia. Dementia had been present in 70% of the cases identified at post-mortem by Petito *et al.* (1985). Moreover, the severity of the pathological lesions correlates not only with clinical evidence of cord damage but also with the presence of dementia (Petito 1988). Sometimes, however, the motor deficit predominates over evidence of cognitive dysfunction, and worsens progressively while mentation is relatively preserved. The similarity with subacute degeneration of the cord had led to the hypothesis of a vitamin B₁₂-deficient aetiology, which has not been substantiated. Nonetheless, abnormalities in B₁₂-dependent transmethylation pathways may be important and CSF S-adenosylmethionine concentrations have been shown to be decreased (Di Rocco *et al.* 2002).

The picture typically evolves over weeks or months as a spastic-ataxic paraparesis, with slowness of gait, clumsiness of leg movements, sensory ataxia and eventual weakness. It may be accompanied by incontinence of the bladder and bowels and by complaints of paraesthesiae or vague discomfort in the legs. Sensation is relatively spared except for loss of vibratory and position sense unless peripheral neuropathy is also present. However, the frequent co-occurrence of the latter may render precise attribution of symptoms difficult.

Spine MRI is typically normal but can reveal non-specific tract hyperintensities. Examination of the CSF may show non-specific abnormalities, including raised protein and a mononuclear pleocytosis. Somatosensory-evoked potentials are useful in tracking the changes in myelopathy. Differential diagnoses must include cord damage due to HSV, VZV and CMV as well as lymphoma in the epidural space.

HIV-associated progressive encephalopathy of childhood

Many children born to HIV-infected mothers develop cognitive and motor disabilities, usually presenting during the first 2 years of life but with wide variability from 2 months to 5 years. Exhenry and Nadal (1996) review the manifestations

of vertical HIV transmission in the CNS; 75% of children with HIV-associated progressive encephalopathy are diagnosed before 3 years (early onset) and 8% after 5 years (late onset). The diagnosis is associated with lower CD4 cell counts in the first year of life and the mean estimated length of survival after diagnosis is 22 months (Lobato *et al.* 1995). The infection is usually acquired *in utero* or possibly during birth. In occasional cases it may have been transmitted postnatally through breast-feeding. Exposure to contaminated blood products accounts for a small proportion of cases, especially those in older children.

Belman (1994) describes the heterogeneous clinical pictures that can result. Common manifestations are developmental delays, cognitive impairment, poor brain growth leading to acquired microcephaly, and corticospinal tract signs. Progressive cognitive impairment is sometimes in the forefront of the picture, whereas other children develop disabling motor involvement while cognitive function remains relatively stable. It has been suggested that cognitive deficits are more frequent than motor deficits in the late-onset group and that CD4 cell count in the first years of life predicts future school adaptation or cognitive ability (Tardieu *et al.* 1987).

The most severe syndrome takes the form of increasing spasticity, impaired brain growth and loss of previously acquired milestones. The progression of decline is usually slow but can be rapid over several weeks. Plateau periods occasionally occur, lasting for several months. The typical result is spastic quadriparesis, sometimes with rigidity, dystonia and tremor, along with progressive apathy and loss of interest in the environment. The characteristic facial appearance is of an alert, wide-eyed child with diminished blinking and a mask-like face.

Most children show a more indolent course, which can be mild with long periods during which progression is halted. Cognitive impairment becomes manifest as a decline in the rate of mental development, but previously acquired milestones are preserved. Motor involvement is again common, with paraparesis or disturbance of gait.

A stable/static form is also recognised in children with histories of developmental delay or non-progressive motor deficits. Intelligence is low but remains relatively stable and neurological deficits do not worsen. Motor dysfunction shows as poor coordination, hyperreflexia and increased tone in the legs. The role of HIV infection is less clear in these cases, but has probably served to compromise normal development.

Neuroimaging in the more severe varieties shows cerebral atrophy that can be observed to progress. White matter hypodensity is often apparent, but the characteristic finding is calcification in the basal ganglia and sometimes also in the frontal white matter. Angelini *et al.* (2000) report that late-onset presentations, after the age of 2 years, were more likely to present polymorphically and less likely to have cortical atrophy on neuroimaging.

Pathology

Post-mortem reveals atrophy on gross examination and may show the characteristic features of adult HIV, with foci of microglia, macrophages and multinucleated giant cells. However, this is found less frequently than in adults. Characteristically the basal ganglia show calcification, chiefly in relation to blood vessels and the adjacent neuropil, and sometimes in the absence of inflammatory change elsewhere. CSF viral load has been associated with atrophy but not intracerebral calcification (Brouwers *et al.* 2000). White matter leucoencephalopathy may be present in the cerebral hemispheres. The spinal cord shows myelin pallor, often restricted in distribution to the corticospinal tracts. Vacuolar myelopathy is infrequent and usually found only in older children. Opportunistic infections and neoplasms of the brain occasionally occur in childhood but less commonly than in adulthood.

Aseptic meningitis

HIV-positive subjects who are not infrequently show a lymphocytic pleocytosis in the CSF during the asymptomatic stage (Marshall *et al.* 1988). Some, however, present with symptoms of meningitis, usually early after infection and while still relatively immunocompetent. Obvious pathogens cannot be isolated, hence the term 'aseptic', but in several cases HIV has been recovered directly from the fluid.

The condition appears to be clinically heterogeneous. In an important group the meningitis develops acutely after infection at the time of seroconversion, presenting with fever, headache, photophobia and meningism (Ho *et al.* 1985). This is typically a mild and self-limiting disorder, lasting for 1–4 weeks, although cranial nerve palsies are occasionally seen. Similar examples may occur later in the asymptomatic phase, or shortly after defining features of AIDS have appeared. Hollander and Stringari (1987) describe two patterns of presentation. One resembles the above, sometimes with recurrent bouts of acute meningeal infection. The other presents with chronic headache in the absence of meningeal signs and may run a protracted course over several months. This appears to represent a more indolent infection, with less marked abnormalities in cell count and protein in the CSF.

A number of case reports have noted the association between oral antibiotic therapy, especially with trimethoprim, and the onset of aseptic meningitis in this setting (Harrison *et al.* 1994).

Peripheral nerve and muscle disorders

Peripheral nerve disorders can complicate all stages of HIV infection and appear to be attributable to a variety of mechanisms (Hoke & Keswani 2005; McArthur *et al.* 2005; Ferrari *et al.* 2006). Evidence of direct infection by HIV is very rare (Pardo *et al.* 2001). As with CNS toxicity, it is likely that HIV proteins indirectly cause injury and loss. For example, there is evidence that upregulation of TNF- α acts as the end-point

of a gp120-activated cascade resulting in apoptosis of sensory neurones (Keswani & Hoke 2003).

Acute and chronic inflammatory demyelinating polyneuropathies.

These are commonest early in the disease and can be the presenting manifestation. The acute form (Guillain-Barré syndrome) can occur at the time of seroconversion. There is profound motor impairment, with loss of tendon reflexes, variable degrees of sensory loss and often radicular pains in the back and legs. The CSF protein is characteristically elevated. The pathogenesis almost certainly reflects a disorder of immune regulation. Treatment by plasmapheresis (Kiprov & Hofmann 2003) or intravenous immunoglobulin can be of benefit. Steroids must only be used with caution and with close monitoring of immune function because they may reduce resistance to opportunistic infections.

Sensory ganglioneuritis and acute cranial nerve palsies. These may also occur in the early asymptomatic phase of infection.

Distal sensory polyneuropathy. DSPN is the main form in the later stages of HIV disease, rivalling HIV dementia in prevalence, with around 30% of hospitalised patients with AIDS being identified as having DSPN. The two frequently occur together. DSPN may develop acutely or gradually, presenting usually with bilateral burning pain and hyperalgesia particularly in the soles of the feet, worse at night or after walking. Intense neuropathic pain may lead to considerable disablement. Mild distal motor involvement can often be found when carefully sought, by way of muscle atrophy or weakness. Tendon reflexes are diminished or absent at the ankles and vibratory thresholds are elevated. Nerve conduction tests show an axonal, length-dependent, sensory polyneuropathy. Occasionally the dysaesthesiae may begin in the hands. The pathogenic factors at work are unclear, and may involve infectious, toxic or nutritional processes.

Distal sensory polyneuropathy is clinically indistinguishable from antiretroviral toxic neuropathy. Some investigators have asserted that antiretrovirals may unmask a silent DSPN. A careful history of treatment and the timings of changes in preparations and doses may help to distinguish aetiological factors. Other causes of neuropathy, such as diabetes, should be excluded.

Other neuropathies. These take the form of polyradiculopathies, consisting of rapidly evolving flaccid paralysis and pain in the back and legs, or sometimes present as a cauda equina lesion. Multiple mononeuropathy (mononeuritis multiplex) appears often to be due to CMV infections, and partial response may be obtained with ganciclovir. HSV is sometimes implicated. The role of direct infection with HIV is suspected, and the virus can sometimes be isolated from the peripheral nerves.

Myopathy. This may present at any stage with slowly progressive proximal muscle weakness of the limbs, myalgia and excessive fatigability. Serum creatine phosphokinase levels are elevated, and cautious treatment with steroids can be beneficial. The relative roles of immunological factors and infection with HIV are uncertain. Other affections of muscle include necrotising myopathy, necrotising vasculitis, nemaline rod myopathy and mitochondrial myopathy. An acute self-limiting myopathic process may also be observed at the time of seroconversion.

Impairment in asymptomatic HIV-positive subjects

In view of the known early invasion of the nervous system by HIV, the question arises whether impairments of a subtle nature may be detectable during the asymptomatic phase. The issue is important for both theoretical and practical reasons. If impairments commonly exist while asymptomatic persons are active at work and in social life, this could be relevant to their competence and reliability. In particular, impairment of judgement, risky decision-making (Hardy *et al.* 2006) or behavioural change could increase their risks of spreading the infection. Early therapeutic intervention might be indicated.

Some reports have identified a higher rate of cross-sectional neuropsychological deficit in asymptomatic individuals compared with those who are seronegative, but there are few studies that reveal that this impairment is progressive or that it precedes MCMD or HAD. In some cases abnormalities in neuropsychological function may not have clinical meaning in the sense that they are not readily associated with functional impact and may improve on retesting. To some extent problems in the sampling of persons to be tested, the selection of appropriate neuropsychological tests (Woods *et al.* 2006), variability in definitions of impairment and disorder between studies, and the need to allow for variables such as past head injury, alcohol or drug abuse, age, premorbid neurological disorders and educational background confound investigations. White, D.A. *et al.* (1995) reviewed the findings of neuropsychological studies between 1987 and 1994. They found that the median rate of impairment was 35% in asymptomatic cases and 12% in controls without the virus. Studies where large batteries of tests were performed were more likely to report impairment.

There has been a search for associations between neuropsychological impairment in asymptomatic HIV infection and various markers. Reports have not found correlations with serum HIV RNA (Dal Pan *et al.* 1998) or CD4 cell count (Podraza *et al.* 1994). CSF viral load has been a more promising indicator (McArthur *et al.* 1997). However, this has not been substantiated in another cohort taking HAART, where there were no differences in serum or CSF viral load or immune activation markers compared with those with

normal neuropsychological tests (J.C. McArthur *et al.*, unpublished results, 2002). It may be that early post-infection viral load and CD4 cell counts are of greater importance in predicting progression to neuropsychological impairment and necessitate early aggressive treatment (Ellis *et al.* 2002; Marcotte *et al.* 2003).

Despite the inherent challenges that have been encountered in establishing the neuropathological correlate of HAD, more encouragingly cognitive impairment does appear to predict histological evidence of HIVE at post-mortem, even when this impairment is mild (Cherner *et al.* 2002). Again, as in dementia, authors have suggested the importance of combining information from several markers of neuronal injury in order to identify the strongest associations with cognitive impairment before death (Moore *et al.* 2006).

Illicit substance and alcohol misuse may be special risk factors for cognitive impairment (Justice *et al.* 2004; Durvasula *et al.* 2006). In one recent study of HIV-positive methamphetamine users, cognitive impairment was associated with severe loss of frontal interneurons (Chana *et al.* 2006). Similarly, viral coinfection, for example with hepatitis C, may worsen neuropsychological performance (Letendre *et al.* 2006; Parsons *et al.* 2006).

With regard to degrees of functional cognitive impairment, it was originally suggested that this is greater in symptomatic cases when compared with asymptomatic controls (Maj *et al.* 1994). However, Heaton *et al.* (1994) identified that, among asymptomatic individuals, the level of unemployment was statistically significantly higher in the cognitively impaired group, in contrast to those unaffected. Albert *et al.* (1995) have replicated this, finding an eightfold increase in work disability, and Heaton *et al.* (2004) have provided further support utilising standardised functional measures that reveal significantly worse performance in neuropsychologically impaired individuals. Memory impairment is clearly an important indicator of decreased likelihood of return to work (van Gorp *et al.* 2007) and has a negative impact on quality of life (Tozzi *et al.* 2003).

An understanding of the progression of cognitive disorders remains elusive. Grant *et al.* (2005) review neuropsychological longitudinal studies in asymptomatic infection between 1990 and 1993. They find that there is little to suggest neuropsychological deterioration in asymptomatic cases up to 36 months follow-up. Longer term, the Multicenter AIDS Cohort Study reports significant decline before AIDS only in psychomotor speed (Selnes *et al.* 1995).

Other psychiatric disorders

In addition to the neuropsychiatric disorders described above, HIV-infected patients are also vulnerable to a variety of psychiatric disturbances, many of which may owe little or nothing to the primary effects of the virus on the CNS. The range is wide, from states of acute distress on becoming

aware of HIV status to profound depression/psychotic illnesses. The latter may sometimes show an admixture of organic psychiatric symptoms, since mood disorder and psychoses can be early manifestations of brain disease. A separate group of patients consists of the 'worried well', i.e. individuals who are not infected but develop an intense fear or even a protracted conviction of harbouring the disease.

Patients with primary mental disorder are also disproportionately represented in those who have contracted the virus. In their retrospective analysis of a psychiatric cohort, Beyer *et al.* (2007) identified that the prevalence of HIV was some four times higher than that of the general population and other studies have supported this finding. The interplay between pre-existing mental illness, HIV-related factors and the effects or interactions of both psychotropic medications and HAART can make psychiatric presentations and management extremely complex. As a result comorbid mental ill health is often poorly recognised in those with the virus (Evans *et al.* 1999).

Other factors have been noted as contributing to psychiatric morbidity over and above the threats inherent in a long-term life-threatening condition. Surveys have stressed the vulnerability of the populations from which HIV-infected persons tend to be drawn, and the powerful role of psychosocial influences in determining adverse reactions (Dilley *et al.* 1985; Faulstich 1987). The acquisition of infection can increase feelings of stigma or guilt, and provoke intense concern about others to whom the disease may have been transmitted. An additional stress is the uncertainty, extending sometimes over many years, about the course the disease will take, occurring often against a background of illness and losses among close friends and partners. In consequence it is scarcely surprising that a high prevalence of psychiatric disorder is reported in both physically asymptomatic and symptomatic persons.

An increasing number of studies have recently focused on the relationship between mental ill health and psychosocial stress on the progression of HIV infection, seeking to find associations between variability in the course of the illness between those affected and the impact of both stressors and mood disorder on cellular immunity and mortality (Ickovics *et al.* 2001; Leserman 2008). Similarly, interest has been directed at the relationship between behavioural manifestations of psychosocial factors and disease progression including the impact of treatment compliance, illicit substance misuse, sexual risk behaviours and physical exercise (for a review see Gore-Felton & Koopman 2008).

Acute psychological reactions

Acute stress reactions are most commonly observed at the time of notification of a positive serological test result. Confirmation of the diagnosis brings the realisation of fears that may have long been present, also the need to tell others, including sexual partners. Lifestyles which have previously

been concealed may be exposed to parents and colleagues for the first time. The principal manifestations are acute shock, bewilderment and anxiety, typically lasting for several weeks. Major depression may be precipitated, with depersonalisation, insomnia and suicidal ideation. A preoccupation may develop with bodily symptoms thought to be indicative of commencing disease. Other reactions include anger, despair, guilt, increased use of alcohol or drugs, social withdrawal or denial. Denial may lead to a dangerous disregard of medical advice and failure to take precautions against infecting others. The incidence of acute psychological reactions at the time of testing has varied widely in different reports, perhaps reflecting the adequacy of pre- and post-test counselling. Perry *et al.* (1990a) found that psychological distress had diminished in most cases by 10 weeks after notification.

Longer-term psychiatric disorder

Longer-lasting psychiatric disorders may emerge during the asymptomatic or symptomatic stages of infection, but it is uncertain whether this is more common than in patients with other serious medical conditions (King 1989, 1993).

Anxiety presents in 4–19% of patients (Justice *et al.* 2004; Pence *et al.* 2006), predominantly in the context of adjustment disorder (Fernandez 2002) and focused on the uncertainties surrounding long-term outcome, the availability of care in the future and the loss of physical and financial independence. The risk of infecting others, or of being identified as homosexual or a drug abuser, may be at the forefront of concerns. Somatic symptoms of anxiety are sometimes interpreted as evidence of progression to further stages of the disorder, giving rise to an escalating vicious circle. Alcohol or drugs may be abused in attempts to self-medicate the symptoms of anxiety.

Depression has a varied reported prevalence, ranging from 2% to 48% of patients in different surveys, depending on those studied (Perkins *et al.* 1994; Fernandez 2002; Chander *et al.* 2006). A moderately high incidence of 15% has been reported in HAART-naïve patients (Starace *et al.* 2002). The risk of depression in seropositive individuals is double that seen in an uninfected control group, independent of sexual orientation (Ciesla & Roberts 2001). In the HAART era, by way of comparison, over 30% of HIV-positive individuals in one large multicentre study met operational criteria for depression (Bing *et al.* 2001). Depression is likely to be underdiagnosed (Asch *et al.* 2003) and has been associated with the presence of personality disorder and low perceived social support (Lyketsos *et al.* 1996). A 2-year prospective cohort study of major depressive disorder in men reported a higher risk of depression in those with more advanced HIV disease at baseline, lifetime presence of multiple psychiatric illness and particularly a past history of

depression as the most significant predictors of depressive illness (Atkinson *et al.* 2008). Interestingly, the presence of baseline cognitive impairment, pathology identified on neuroimaging and adverse life events did not predict a depressive episode in this study, although it is acknowledged that this may be a feature of the cohort and needs further confirmation.

Depression and withdrawal can significantly interfere with the ability to cope with the procedures required for management of the illness (Ostrow 1990; Cruess *et al.* 2003; Antoni *et al.* 2005) and particularly with adherence to antiretroviral treatment regimens (Avants *et al.* 2001; Starace *et al.* 2002; Tucker *et al.* 2003). It would appear that taking antidepressant medication could improve treatment adherence in depressed subjects, although further investigation is needed to elucidate whether treatment of depression is related to HIV outcomes (Yun *et al.* 2005). There is increasing, if sometimes conflicting, evidence of the negative impact of depressive disorders on immunological, virological and clinical outcomes in HIV even when controlling for poor HAART adherence (Cruess *et al.* 2003; Hartzell *et al.* 2008). Prior to the advent of HAART, the San Francisco Men's Health Study found that depressed individuals at baseline progressed to an AIDS diagnosis roughly 1.5 years sooner than their non-depressed counterparts (Page-Shafer *et al.* 1996). This finding has been corroborated and refuted by subsequent pre-HAART studies. Notably, the Multicenter AIDS Cohort Study (Lyketsos *et al.* 1996) did not find a significant association. Similar studies in the era of HAART, conducted over longer follow-up periods and with larger numbers, have found more consistent evidence for an association between chronic depressive symptoms and less favourable outcomes (Leserman 2008). Nonetheless, it appears that HAART does have a modest impact on reducing measures of depression and hopelessness (Rabkin *et al.* 2000).

Care in identifying depression is particularly important and especially in the context of the overlap of somatic symptoms such as fatigue, pain, appetite loss and sleeplessness that may be present throughout infection with HIV. Nonetheless, severe depressive symptoms should not be assumed to be understandable and justified, and must always receive full evaluation and treatment. Anhedonia and diurnal mood variation may be useful discriminating symptoms suggestive of depression (Treisman *et al.* 2001). The problems that may arise in distinguishing depression and the early stages of HIV-associated dementia are discussed under HIV-associated cognitive disorders in this chapter.

Obsessive-compulsive disorder. This can occur with or without depressed mood, commonly involving repeated bodily scrutiny for evidence of progression of disease. Obsessive ruminations may centre on death and dying, or endeavours to recollect past sexual partners to whom the infection may have been transmitted.

Suicide. This presents a considerable risk in both the early and late stages of the disorder. Perry *et al.* (1990b) found that suicidal ideation was common, affecting almost 30% of individuals at the time of serological testing, but falling significantly within 2 months of notification. Suicide attempts tend to cluster in the first 6 months after diagnosis, underlining the importance of pre- and post-test counselling (World Health Organization 1990b). Demographic and disease-related factors associated with suicidality have been identified as white ethnicity, male gender, homosexuality, physical health complications, frequency of AIDS-related conditions and rapidity of disease progression. Psychosocial variables associated with suicidal ideation include neuroticism, hopelessness, avoidant coping, intravenous drug use, limited social support networks and a family history of suicide (Kalichman *et al.* 2000; Haller & Miles 2003; Carrico *et al.* 2007).

Later, with symptomatic AIDS, completed suicide is considerably increased. Rates among New York residents were estimated to be some 36-fold above expectation in one retrospective review, but such a very large excess has yet to be confirmed (Marzuk *et al.* 1988; Marzuk 1991). An important consideration is the extent to which suicide in the later stages may be considered to be 'rational' in view of the poor outcome to be expected. Against this is the close association between suicide and psychiatric illness, inappropriate guilt, and erroneous perceptions about the development of the illness and methods available to relieve suffering (Glass 1988; King 1993).

Marzuk (1991) discusses other AIDS-related suicides, including persons grieving for loss of friends and family members, psychotic patients who were deluded that they suffered from AIDS, and a small group of people, mainly homosexual, who had deliberately sought to contract AIDS as a means of ending their lives.

Psychoses. These appear to be not infrequent, although the scattered reports of small numbers of cases make any estimate of prevalence uncertain and it is certainly considerably less than that of depression. Many pictures have been reported, some seemingly typical of psychoses occurring in other settings, while others have shown special features.

A considerable proportion of psychoses develop in the context of AIDS-related cognitive impairment (Sewell *et al.* 1994; Evans *et al.* 2002) and in one study 15% of patients with HAD reported psychotic symptoms (Navia & Price 1987). In others, evidence of cognitive impairment emerges only later when the more florid manifestations have been brought under control. Sometimes, however, organic symptomatology remains absent throughout the illness which presents as a purely 'functional' psychosis (Halstead *et al.* 1988) and on occasion the only indicator of underlying HIV infection.

Maj (1990) reviews the mechanisms that may be responsible: chance association, reactions to the threat of the dis-

order, precipitation in predisposed persons or a response to drugs abused or prescribed. Alternatively, the psychosis may reflect HIV brain infection, especially in patients with no previous history of psychiatric illness or drug abuse and who are unaware of their seropositivity (Buhrich *et al.* 1988). The predilection of the virus for the limbic regions of the brain could be relevant in this regard. De Ronchi *et al.* (2000) identified psychiatric history, lower cognitive performance and the absence of antiretroviral treatment as potential risk factors for first-episode psychosis in those with HIV infection compared with non-psychotic controls and suggested that HAART may be protective against psychosis. However, antiretrovirals have also been repeatedly implicated in the development of psychotic disorders in the literature. Foster *et al.* (2003, 2004) report the emergence of two cases of psychosis that they suggest were associated with abacavir in a combination regimen. Zidovudine (Maxwell *et al.* 1988; O'Dowd 1988; Schaerf *et al.* 1989), efavirenz (De la Garza *et al.* 2001; Peyriere *et al.* 2001) and nevirapine (Wise *et al.* 2002) are also identified in this review as being associated with *de novo* psychoses (Foster *et al.* 2003).

The variety of pictures encountered is illustrated by several reports and reviews (Thomas & Szabadi 1987; Buhrich *et al.* 1988; Halstead *et al.* 1988; Vogel-Scibilia *et al.* 1988; Harris *et al.* 1991). Delusions, hallucinations, bizarre behaviour, thought disorder, lability of mood and major affective disorder may feature prominently, with or without organic accompaniments in the mental state. Among the 31 cases reviewed by Harris *et al.* (1991), after excluding those due to substance abuse or delirium, the psychosis was the presenting feature in 12. CT was abnormal in half and the CSF in one-quarter, these patients tending to decline rapidly in physical and cognitive status.

It seems unlikely that a specific 'HIV psychosis' exists, but it appears that *mania* may be especially common and perhaps associated with HIV disease progression. In the early stages of HIV infection the incidence of manic episodes is likely to be similar to the seronegative general population at 1–2% (Lyketsos *et al.* 2001). This increases some fourfold at the onset of AIDS and is associated with cognitive impairment and higher CD4 counts (Lyketsos *et al.* 1993). Kiebertz *et al.* (1991) described eight such patients, all with evidence of cognitive impairment once the florid mood symptoms had subsided. Irritability was more prominent than elation, and all showed MRI abnormalities. King (1993) reported that all psychotic patients referred to his AIDS liaison psychiatry service exhibited major manic symptoms. Treisman *et al.* (1994) present data suggesting that when mania develops in patients with low genetic risk this tends to occur late in the disease and in the context of dementia, whereas in those with personal or family histories of affective disorder mania may occur at any stage and while cognitive function is well preserved.

The 'worried well' (AIDS phobia, pseudo-AIDS)

The intense public concern aroused by AIDS, and the amount of media attention devoted to it, have raised anxieties in many segments of the population. People at risk, particularly homosexual and bisexual men, may present themselves for testing in states of considerable alarm (termed 'AIDS anxiety' or 'AIDS panic'). Psychotic patients may incorporate AIDS into their delusions and become convinced that they are harbouring the disease (Mahorney & Cavenar 1988). Todd (1989) describes typical examples: patients present with anxiety or panic after casual affairs, especially in the face of mild physical symptoms, or with obsessional fears of touching people and compulsive hand washing, or with paranoid psychosis developing some time after an affair.

Distinct from these are a group of neurotic patients who focus on the condition as a vehicle for hypochondriacal concern. Such patients can absorb a great deal of attention in fruitless attempts at reassurance. These are the 'worried well'. They are remarkable not only for the persistence of their anxieties, which can fail to be allayed by repeated negative tests, but often for the remoteness of the chance that they have been exposed to risk of infection. An interesting constellation of influences appears to underlie this sometimes intractable disorder.

Miller *et al.* (1988) reported experience with 19 such patients. Of the 17 males, six were heterosexual, eight homosexual and three bisexual. The mean age was 35 years. The uniform presentation was with an unshakeable and anxiety-laden conviction that they had HIV infection or disease, as indicated by symptoms such as fatigue, dizziness, sweating, skin rashes, muscle pain, diarrhoea, sore throat, slight weight loss, minor mouth infections or slight lymphadenopathy. The misattribution of such features had often stemmed directly from media reports describing AIDS-related symptoms. Obsessional ruminations were almost universal, centring on thoughts of HIV disease and death, possible 'high-risk' sexual practices in the past and the dangers they may have presented to others. Repeated body checking for signs of the disease and palpation for enlarged lymph nodes were common, likewise questioning and scrutiny of spouses or partners for evidence of the disease. Three-quarters were depressed and over half suicidal. Two patients later progressed to a delusional conviction of supposed infection. Most of the patients had already made repeated attendances at clinics or general practice surgeries, often receiving several negative serological test results.

Background features included a fairly consistent picture of constrained and problematic sexual adaptation, including non-acceptance of homosexual tendencies, difficulties with sexual expression, or constricting religious or family influences on sexual behaviour. This had often resulted in episodes of covert sexual activity, either homosexual or heterosexual, with high levels of associated guilt. In most

cases there was a history of no more than low-risk sexual experiences, and only two patients reported activities that could have led to infection within the previous 6 years. A past history of psychiatric disorder, mostly depression or anxiety, was common.

The remarkable persistence of such anxieties has been stressed in most reports. Negative test results may be attributed by the patient to laboratory error, to the appearance of a 'new form' of the virus, or to their inability to form antibodies as other people do (Maj 1990). Miller *et al.* (1988) acknowledge the futility of repeated reassurance, which appears merely to maintain the problem. They recommend a cognitive-behavioural strategy based on cue exposure and response prevention, with attempts at the reinterpretation of symptoms in terms of their origin in anxiety. In occasional patients, however, the excessive fear of infection may prove to be part of a major depressive illness and be responsive to antidepressant medication (Jenike & Pato 1986).

Factitious/fraudulent AIDS

In contrast to the above group who have an unfounded fear of infection, occasional patients present with unfounded claims of having the disease. Some state that they are HIV positive to secure financial assistance, rehousing or social support (King 1993). Drug abusers may hope to ensure a supply of maintenance medication and obviate therapeutic attempts to promote withdrawal. Falsified documents and forged reports may be presented to these ends (Zumwalt *et al.* 1987).

More remarkable are those patients who attend hospitals and clinics with a complex history of HIV-related illness, including opportunistic infections and their treatment, all of which turns out to have been fabricated. Sometimes a similar story has been repeated during visits at several hospitals. These patients represent a variant of Munchausen's syndrome, the underlying motive being apparently to secure medical attention. Zuger and O'Dowd (1992) describe such a patient who had received inpatient and outpatient treatment at AIDS facilities for almost a year before the true situation was established. They review 14 more cases from the literature. The usual presentations were with acute neurological or psychiatric complaints, and most patients were members of groups at high risk for HIV infection. Only HIV testing, and where possible confirmation of the history, can protect against a false diagnosis.

Bereavement and stressful life events

Fawzy *et al.* (1991) describe the multifaceted problems of bereavement in patients with AIDS, also in their families, friends and partners. In contrast with individuals suffering from other life-threatening diseases, the patient with AIDS will often have to deal with AIDS-related deaths among many associates and in unrelenting succession. Such an experience of loss of a partner or close friend has been associated with a more rapid decline in CD4 counts in surviving

HIV-positive homosexual men (Kemeny *et al.* 1995). The immune activation marker neopterin is increased and natural killer cell cytotoxicity decreased in bereaved survivors (Kemeny *et al.* 1995; Goodkin *et al.* 1996).

There is a high risk of the development of abnormal bereavement reactions for a number of reasons. There may be constraints on the public display of grief when homosexuality has previously been concealed, and in the case of drug abuse there is likely to be disapproval or even a punitive response from those around. The patient's ambivalent feelings about homosexuality or drug abuse may be brought to the surface, and may conspire against the development of new supportive relationships. Family members may need to contend with the first awareness of their relative's sexual orientation or drug abuse, and may find themselves lying about the cause of death. Health-care workers who treat patients with AIDS also carry a heavy burden in adjusting to the loss of their patients.

In general, stressful life events have been repeatedly shown to have significant effects on disease progression (Leserman 2008). In one study of young people, two or more stressful events were associated with three times the risk of decline in CD4 counts over the period of follow-up (Howland *et al.* 2000). Similarly, in adult homosexual men, higher cumulative stressful event scores predicted an accelerated transition to AIDS (Leserman 2000). Since the more widespread use of HAART, negative effects of stress on immunological, virological and clinical outcomes have continued to be reported (Ironson *et al.* 2005a,b,c; Leserman *et al.* 2007).

Investigation and treatment

The attention of physicians, psychiatrists, psychologists, social workers and specially trained counsellors may be required in HIV-related disease. The problems that arise are frequently complex, in terms of both medical diagnosis and psychosocial impact. Investigations during the symptomatic stages will often involve extensive laboratory and radiographic procedures. Some of the principal findings in patients with opportunistic infections and tumours of the nervous system have been mentioned above, also findings in relation to HAD.

Serological testing and pretest discussion

The Clinical Effectiveness Group of the British Association of Sexual Health and HIV produced UK National Guidelines on HIV testing in 2006 (Rogstad *et al.* 2006) and these should be referred to with regard to all matters relating to serological testing.

The technique routinely employed for detecting HIV infection relies on assessment of antibodies to the virus using fourth-generation enzyme immunoassay (EIA) that detects all three main immunoglobulins and p24 antigen. When a positive result is obtained the test is first repeated, then checked with a more specific approach such as immunofluo-

rescence, radioimmune precipitation or Western blotting and laboratories should have a confirmatory algorithm for such testing (Parry *et al.* 2003). Testing using PCR can be utilised during this period and may identify infection 7–10 days earlier than EIA screening. Lymphocyte culture for isolation of the virus can be useful in paediatric practice, since HIV antibody testing can remain positive through passive maternal transfer for up to 18 months. Minute amounts of HIV nucleic acid can be detected by PCR, and this can yield a measurement of viral load. Oral fluid samples can also be tested, although antibodies may take longer to become positive.

Testing should only be carried out with the patient's *informed and explicit* verbal consent, except in very rare instances, and this should be carefully documented following a pretest discussion with a professional who has specific training and expertise in HIV counselling. A positive result carries not only implications for the patient's future health but also far-reaching social, financial and often legal consequences. The specific points to be covered in the pretest discussion have been set out in the UK National Guidelines (Box 7.3).

However, there are very exceptional circumstances in which testing may need to be performed without explicit consent, namely where a test is imperative in order to secure the safety of persons other than the patient and where it is not possible for the prior consent of the patient to be obtained, for example if the patient is unconscious (General Medical Council 1988, 1993, 1997). Patients should be informed that they have been tested and why the test was performed once they regain consciousness. The result should not be disclosed to anyone (including relatives) who is not involved in their health care without the patient's permission. In psychiatric practice other situations may also arise, for example when a patient is unable or unwilling to give consent by reason of

psychiatric disorder such as severe affective illness, mental handicap or an organic brain syndrome. It is then necessary before proceeding to be clear that the result would be of both real diagnostic value and likely of benefit to the patient. In many instances there is no immediate and pressing need for a definitive diagnosis, and it may be possible to defer testing until the patient becomes well enough to reconsider giving consent in the normal way. The need to know urgently for the protection of staff or other patients is likely to apply only in patients showing aggressive or seriously disinhibited behaviour.

When performed without consent, it is important to record reasons for taking such action in the patient's notes, to discuss it with the psychiatric team and to obtain a second opinion from a psychiatrist or physician. It is wise also to inform the health authority's solicitor and the relevant medical defence body. In essence the test should be carried out with awareness that the decision may have to be defended in court.

Matters of confidentiality surrounding the test result can also be problematic (General Medical Council 1988, 1993, 1997; Catalan *et al.* 1989; Rogstad *et al.* 2006). Only those team members who need to know should be informed. The importance of telling the patient's general practitioner, who is likely to be involved in future care, should be discussed with the patient and consent obtained for this. However, if after full discussion the patient refuses, his request for privacy should normally be respected. The exception is when failure of disclosure could put the health of any carer at serious risk although this needs to be considered in the context of the legal framework of the jurisdiction of the test. This is particularly so when the patient is incapacitated and cannot give consent. A careful multidisciplinary discussion and consultation with both an occupational health consultant and legal advice should be sought when making complex testing decisions. Similarly, disclosure to a spouse or partner without consent is warranted only when there is a serious and identifiable risk to a specific individual who, if not informed, would be exposed to infection.

Treatment

General aspects

General aspects of management include the need for support and counselling, not only for the infected person but often also for the family, partners and friends. Even in the asymptomatic stage it is important to allow full discussion of the disease and its significance, including the likelihood that there may be considerable delay before symptoms make an appearance. It is essential to provide detailed information about methods to minimise the risk of infecting others, including 'safe' sexual practices and, in addicts, the strict avoidance of needle-sharing. The patient should be advised to inform the dentist before any dental procedure.

Prophylactic drug treatment is often undertaken to ward off opportunistic infections such as *Pneumocystis carinii*,

Box 7.3 Specific points to be covered in the pretest discussion (Rogstad *et al.* 2006)

- 1 Benefits of testing:
 - (a) Health benefits of current treatments
 - (b) Knowing HIV status can allay anxiety
 - (c) A positive test may motivate people to reduce risk activities
 - (d) Opportunity to reduce the risk of transmission to others, e.g. infants, sexual partners
- 2 Risk assessment, including date of last risk activity
- 3 The 'window period'
- 4 The implications of testing for mortgages, insurance, occupational risks and confidentiality
- 5 Details of how the result will be given
- 6 Where appropriate to explore support and coping mechanisms
- 7 Obtaining informed consent for the test
- 8 Information about HIV transmission and risk reduction as necessary

tuberculosis and toxoplasmosis (Beiser 1997). Problems over employment and coping with negative reactions from associates will often need attention. Many patients will benefit from regular follow-up, when weight and blood counts can be checked routinely and enquiry made about general health and fitness. Referral to local self-help organisations will usually be of very considerable assistance.

Management of major psychiatric disorders

Depression and stress. Ferrando and Freyberg (2008) critically review the treatment of depression and identify the confounding factors in appraising the literature. Both open label and randomised controlled trials disproportionately represent homosexual and bisexual men, have variable inclusion and outcome criteria, focus on different stages of HIV disease and fail to focus on medication interactions. They found fairly consistent evidence (based on randomised clinical trials) that selective serotonin reuptake inhibitors (SSRIs), particularly fluoxetine, and the tricyclics imipramine and desipramine (Zisook *et al.* 1998; Rabkin *et al.* 1999), are effective, with a preference for SSRIs based on their favourable side-effect profile and lack of any demonstrable effect on immune status (Fernando & Freyberg 2008). Other antidepressants, including mirtazapine, have also shown promise in open label studies. Rabkin *et al.* (2004) have identified the effectiveness of testosterone, particularly for fatigue, in depressed HIV-positive men. Dexamfetamine (Wagner & Rabkin 2000), modafinil (Rabkin *et al.* 2004) and methylphenidate (Fernandez *et al.* 1995) have also shown benefit in depression and particularly in improving fatigue and demotivation.

When prescribing antidepressants it is always important to consider interactions with antiretrovirals. Protease inhibitors and nucleoside reverse transcriptase inhibitors can affect cytochrome P450 activity, resulting in altered metabolism of some antidepressant medications. Fluoxetine has been shown to cause increases in ritonavir levels. Venlafaxine, which has a more negligible effect on P450, has a potentially smaller effect on HAART (Ereshefsky & Dugan 2000) but can lower plasma levels of indinavir.

The study by Markowitz *et al.* (1998) compared combined psychological and pharmacological treatments with different modalities of psychotherapy for depression comorbid with HIV. This found that the group on combination treatment and that receiving interpersonal therapy had significant improvements in depression scores compared with supportive and cognitive-behaviour therapies. Group psychological interventions have been more extensively investigated, both alone and in combination with antidepressants, and have suggested an effect of psychotherapies alone, at least in mild to moderate depressive episodes (Targ *et al.* 1994; Zisook *et al.* 1998; Laperriere *et al.* 2005).

A meta-analysis of stress management interventions in HIV-positive adults, conducted by the National Institutes of

Health (Scott-Sheldon *et al.* 2008) found that such interventions significantly improve mental health indices and quality of life but do not impact on immunological outcomes or hormonal processes, a finding echoed by Brown and Venable (2008).

Psychosis. The evidence base for treating psychotic disorders in HIV-positive individuals is poor in comparison with mood disorders. It is likely that patients with HIV infection are considerably more sensitive to extrapyramidal effects which, alongside the subcortical psychomotor retardation associated with the virus, may be considerably disabling. For this reason, low doses and slow titrations of antipsychotics are advised, with careful monitoring for metabolic syndrome (Repetto & Petitto 2008). Interactions between HAART and antipsychotics should again be carefully considered. Ritonavir has been shown to decrease plasma concentrations of olanzapine (Penzak *et al.* 2002).

Mania. Mood stabilisers have been investigated in the management of manic symptoms associated with HIV. Sodium valproate has been suggested to increase HIV replication in some studies (Moog *et al.* 1996), although this has not been duplicated in studies looking at the drug's effect on viral load in serum and CSF (Maggi & Halman 2001; Ances *et al.* 2006). Carbamazepine and lamotrigine are both known to have effects on the enzyme systems also utilised by antiretrovirals, resulting in altered serum concentrations of both mood stabiliser and/or antiretroviral. Careful monitoring is essential. Zidovudine has been shown to have a protective influence against mania (Mijch *et al.* 1999).

Treatment of opportunistic infections, neoplasms and neuropsychiatric complications

This is a matter for specialist attention. The differential diagnosis is often wide, infections can be multiple and investigations may need to be extensive. PCP will often respond, at least early on, to co-trimoxazole, and Kaposi's sarcoma skin lesions to local radiotherapy or intralesional injections of vinblastine. Kaposi's sarcoma occurring elsewhere, such as the lungs or gastrointestinal tract, may be treated with intravenous chemotherapy. Oral candidiasis may be kept in check with nystatin suspension or amphotericin lozenges; oesophageal and severe oral infection will require ketoconazole. Details of treatment for these and other systemic infections are given in textbooks of medicine.

Many CNS pathogens can be treated similarly; for a succinct review, see the European Guidelines compiled by Portegies *et al.* (2004). *Toxoplasma* brain infection will often respond, both clinically and radiologically, to pyrimethamine and sulfadiazine, occasionally with complete resolution of symptoms and control of the disease. Improvement can be seen within 1–2 weeks, this sometimes being used empirically as a diagnostic test. If there is no response, biopsy

is required to investigate for other treatable conditions such as lymphoma, tuberculosis or CMV infection. Cryptococcal infection is usually treated with amphotericin, with or without 5-flucytosine, followed by maintenance therapy with fluconazole (Manji & Connolly 1992). HSV requires acyclovir, and CMV infection foscarnet or ganciclovir; the latter should not be combined with zidovudine because of severe myelosuppression. Cerebral lymphoma often responds initially to radiotherapy.

Inflammatory neuropathies are sometimes considered best treated with plasmapheresis because of the risks of steroid therapy in the immunocompromised patient. Others, however, use steroids on the basis that autoimmune mechanisms are at work. Distal sensory neuropathy may respond to zidovudine.

Highly active antiretroviral treatment

There are four classes of antiretrovirals that are in current use: nucleoside/nucleotide analogue reverse transcriptase inhibitors (NRTIs), non-nucleoside analogue reverse transcriptase inhibitors (NNRTIs), protease inhibitors and fusion inhibitors. A full review of their mechanisms of action and the evidence that supports their use can be found in Warnke *et al.* (2007) and is only discussed briefly here.

The NRTIs are similar to the nucleoside building blocks of DNA and RNA and act by affecting reverse transcriptase activity through direct competition with nucleosides to be incorporated into viral DNA. The first NRTI, zidovudine (3-azido-2,3-diethoxythymidine, AZT, Retrovir, ZDV), has been used in treatment since 1987. It is a thymidine analogue. It is highly active against HIV *in vitro*, but is effective only against virus in the process of replication, after it has been phosphorylated. Resistant strains may accordingly develop after several months of use. It is of particular interest as it is one of the antiretrovirals that crosses the blood–brain barrier. The most frequent adverse effect of zidovudine is bone marrow suppression, resulting in anaemia or neutropenia, which may dictate dose reduction or cessation of treatment. Regular monitoring of the blood picture is therefore essential during treatment. Other side effects include nausea, anorexia, abdominal pain, rashes, headache and insomnia, largely restricted to the early weeks of treatment. A reversible myopathy occasionally develops after long-continued use.

Other NRTIs that penetrate the CNS include abacavir, didanosine and stavudine. One study of HAART combinations in HAD found that adding abacavir did not result in improved clinical or virological outcomes, although this may have been confounded by the short duration of HAART, which arguably would have not stabilised prior to the addition of abacavir (Lanier 2001). Stavudine has been shown to further ameliorate neurological symptoms in patients previously treated with zidovudine (Arendt *et al.* 1998). CSF viral load has been shown to be decreased to undetectable levels with stavudine (Gisolf *et al.* 2000).

The NNRTIs include nevirapine, delavirdine and efavirenz. These antiretrovirals act by directly binding to reverse transcriptase and subsequently block DNA polymerase activity. They do not require phosphorylation to become viricidal unlike the NRTIs. All three penetrate the blood–brain barrier, although clear evidence about their benefits in HAD remains to be established. Efavirenz has been shown to decrease CSF viral load (Tashima *et al.* 1999) and cognitive improvements have been noted with nevirapine/efavirenz combinations (von Giesen *et al.* 2002). However, efavirenz has also been associated with a number of neuropsychiatric side effects including dizziness, agitation, hallucinations, amnesia, insomnia, nightmares and deterioration in existing psychiatric illness. Of interest to the psychiatrist, it has also been shown to produce false-positive results in testing for cannabinoids.

The protease inhibitors inhibit HIV-1 protease, an enzyme responsible for cleavage of the virus into smaller functional units. Indinavir crosses the blood–brain barrier.

Several new classes of antiretroviral have been, or are in the process of being, developed. Of these, the fusion inhibitor enfuvirtide acts by altering the conformation of the helical protein that allows virus–host cell fusion. Integrase inhibitors, CCR5 receptor antagonists and maturation inhibitors are all under development.

It remains unclear whether using antiretrovirals with CNS penetration is necessary to effect improvements in neuropsychiatric symptoms. Letendre *et al.* (2004) found a correlation between the suppression of CSF viral load and the number of blood–brain barrier-penetrating antiretrovirals in the combination used. This correlation was not substantiated in another study (Antinori *et al.* 2004). Robertson *et al.* (2004) identified that a change of HAART regimen alone had an impact on neurological symptoms, regardless of whether CNS-penetrating drugs were included in the combination.

Syphilis of the CNS

Syphilitic infections of the nervous system have decreased tremendously during the last century and particularly since the introduction of penicillin. Despite the mandatory surveillance of sexually transmitted diseases in many countries, very little detailed information is available regarding the epidemiology of neurosyphilis. In the UK between 1936 and 1939 there were 1629 deaths registered as due to general paresis or tabes, but by 1966–1969 these had fallen to 224 (Wilkinson 1972).

Primary (infectious) syphilis had already shown a gradual decline from the time of the First World War onwards. A new peak arose during the Second World War but this subsided rapidly in the years that followed. However, it was feared that late manifestations would ultimately rise again, due to unwitting partial treatment in the early stages when penicillin was given for other conditions, but this did not occur.

What does seem to have happened is that partial but incomplete suppression of infection led to neurosyphilis appearing later in atypical and attenuated forms, with consequent difficulty in diagnosis in many instances. There has also been a pronounced shift away from parenchymatous neurosyphilis (general paresis and tabes dorsalis) towards meningovascular syphilis, which now accounts for most of the new cases encountered (Nieman 1991). Cases of infectious syphilis declined during the 1980s in association with the behavioural changes associated with the HIV pandemic. By the early 1990s case numbers had stabilised and although both low incidence and prevalence were evident, syphilis had not been altogether eliminated. In 1997, there were reports of an outbreak of syphilis among heterosexuals in Bristol and a subsequent increase in incidence (Simms *et al.* 2005). This coincided with similar outbreaks in Europe, North America and Australia. In the UK, London and the north-west of England had the highest incidence, from data reported up to the end of 2005 (Health Protection Agency 2006). In England and Wales, the highest number of cases are reported in men who have sex with men, where white ethnicity and HIV coinfection are the most common associations (see Neurosyphilis and HIV coinfection, later).

Paradoxically, the success of treatment brings its own particular risks, since as the disease becomes increasingly rare it runs the hazard of being more often overlooked. The psychiatrist must continue to bear it in mind, to check regularly with serological tests and look carefully for cardinal signs in the pupillary reactions and tendon reflexes. The 'classic presentation' of general paresis is nowadays rare, and syphilis of the CNS can present with virtually any form of psychiatric complaint.

Traditionally, the effects of syphilis are divided into four stages: the primary stage with the appearance of an ulcer or chancre at the site of inoculation; the secondary stage with early generalised lesions, chiefly manifest as a variety of skin and mucous membrane lesions that appear within 4–10 weeks; the tertiary stage with the appearance of late destructive lesions such as gummata, gummatous ulcers, glossitis and bone changes; and the quaternary stage of parenchymatous changes in the CNS leading to tabes dorsalis and general paresis. These divisions are empirical, and with the exception of the last not easily applied to the spectrum of changes that occur in the CNS. Whether the existing nomenclature for classifying cases of neurosyphilis is adequate has been questioned by Timmermans and Carr (2004) in their discussion of a recently reported case series. They propose a clinically based, syndromic classification whereby cases would be identified by their associated clinical presentations, i.e. 'neurosyphilis with seizures . . . with stroke . . . with cranial nerve involvement'. For practical purposes the clinical presentations of neurosyphilis can also be divided into early and late (Marra *et al.* 2000). Early neurosyphilis refers to CNS

involvement during the early manifestations of the disease and largely reflects involvement of meningeal and vascular structures. Meningovascular syphilis can appear in the secondary or tertiary stages, and even with primary infections the nervous system is sometimes involved without overt signs of disorder. In more recent cohorts neuropsychiatric presentations have been identified as the most frequently reported cluster, with 50% of cases presenting symptoms such as psychosis, delirium or dementia (Timmermans & Carr 2004). The effects of syphilis on the spinal cord (myelitis, cervical pachymeningitis and syphilitic amyotrophy) are the province of neurology and are not dealt with here.

After infection, around 25% of cases result in treponemal invasion of the CSF. The majority of patients, including those coinfecting with HIV, show spontaneous resolution of CNS involvement, even in the absence of treatment (Marra *et al.* 1996).

Early asymptomatic neurosyphilis

This term is used for cases with abnormalities in the CSF but no symptoms or signs of CNS disorder. The cells or protein may be raised, the pressure increased or CSF immunological tests may give a positive result. Such findings emerge in approximately 10% of cases of primary syphilis and 30% of cases of secondary syphilis when the CSF is examined routinely (Hahn & Clark 1946a). Such CSF findings are more complicated to interpret in the presence of HIV coinfection (Zetola & Klausner 2007).

Thus it appears that a meningeal reaction can set in very early in a surprising number of cases and without producing overt disorder. When adequate treatment is given the disturbance dies out within a year or two and proves to have been benign. In some cases the prognosis is favourable even when treatment has been inadequate (Hahn & Clark 1946b), though in others the changes probably have implications for the later development of quaternary neurosyphilis.

Acute syphilitic meningitis

In rare cases infection of the nervous system may be overwhelming, with the production of an acute meningitis. This usually develops within the first 2 years, and can even accompany the secondary rash within a month or two of the primary infection. The illness is indistinguishable from other forms of acute meningitis until specific tests are performed.

There is a pyrexia of approximately 39°C (102°F), with headache, delirium, neck stiffness and somnolence. Lumbar puncture reveals fluid under pressure, containing upwards of 1000 cells/mm³, of which a considerable proportion may be polymorphs. Specific tests for syphilis may be negative in the CSF but are invariably positive in the blood. With prompt treatment there is usually good recovery, although some permanent intellectual impairment may result.

Subacute and chronic meningovascular syphilis

A variety of clinical pictures are subsumed under this heading and are most easily understood in terms of the underlying pathology. The disorders, which represent 10–35% of cases of neurosyphilis, usually declare themselves 4–10 years after the primary infection. Although peak occurrence is at 7 years, the range may extend from the first few months to 30 years or more (Lukehart *et al.* 1988).

Pathology

Changes affect the meninges, cerebral vasculature and spinal cord resulting in transient or permanent ischaemic events (Tramont 2005). In the meninges there is a diffuse inflammatory process with thickening, areas of necrosis and the formation of exudate, which may become gelatinous and adherent (gummatous leptomeningitis). Changes are often most in evidence at the base of the brain, resulting in cranial nerve lesions or hydrocephalus due to obstruction of flow of CSF. Less commonly they are localised over the convexity, or extend to envelop the whole of a hemisphere in a thickened sheath. Similar changes may extend along the perivascular channels, with the formation of localised gummata within the brain or in relation to the overlying bones of the skull.

Vascular pathology forms an integral part of the reaction in the meninges but can also involve the cerebral vessels directly. The vessels at the base of the brain are chiefly affected, first the small and then the larger branches of the circle of Willis. There is both a periarteritis and an endarteritis, the latter producing great hypertrophy of the intimal layer and leading to thrombosis. Around affected vessels there is fibroblastic proliferation and necrosis, again sometimes proceeding to scattered gummata. The large isolated gumma leading to tumour-like symptoms is extremely rare.

Clinical features

Subacute forms of meningitis may progress rapidly once they are declared, though chronic forms are often insidious and intermittent, with periods of several months between exacerbations of disease; hence the delay which may be encountered in diagnosis.

Prodromal symptoms consist of intermittent headache, lethargy and malaise. The patient is usually slow and forgetful, with difficulty in attention and concentration and impaired judgement. Emotional instability and irritability are common together with changes in personality. Mental deterioration may progress to definite evidence of dementia, sometimes with fleeting delusions or episodes of excited overactivity. Alternatively, there may be periods of clouding of consciousness or florid delirium separated by intervals of relative normality. The vague quality of the complaints, and the fleeting nature of the early disabilities, can lead to the

organic nature of the disturbance being overlooked for some considerable time.

The focal evidence of basal meningitis consists chiefly of cranial nerve disturbances. The facial and auditory nerves are frequently affected and sensorineural deafness occurs in up to 20% (Singh & Romanowski 1999). Optic neuritis and iritis can present as features (Margo & Hamed 1992). Paresis of external ocular movements and abnormalities of pupil size and reaction are common, but the fully developed Argyll Robertson pupil is rarely seen. Papilloedema, optic atrophy and visual field defects from chiasmatic lesions also occur. Hypothalamic involvement may produce polyuria, obesity and somnolence. Convexity meningitis can result in focal fits, aphasia or hemiparesis. Headache is often sharply localised and the overlying skull may be tender.

When vascular pathology is predominant, minor arterial occlusions lead to episodes of transient neurological disorder: hemiparesis, hemianopia, aphasia or amnesia. Asdaghi *et al.* (2007) report two cases, both lacking a history of symptoms of systemic syphilis, of meningovascular syphilis presenting with headache and multiple cerebrovascular attacks. Occlusion of major vessels, predominantly the middle cerebral artery but also the basilar circulation, can result in a completed stroke (Flint *et al.* 2005). The picture of pseudobulbar palsy may also develop, with bilateral spasticity and emotional lability. Unusual presentations include isolated ocular palsy and trigeminal neuralgia as well as meningitic symptoms (Nieman 1991). Meningovascular syphilis may also mimic encephalitis and even multiple sclerosis. It should be considered in any acute encephalopathy, and in any acute stroke in younger patients, regardless of whether there is a clear history of systemic syphilis.

The CSF shows a moderate cellular reaction with up to 200 cells/mm³, mostly mononuclear leucocytes, and a moderate increase in protein. The pressure is usually normal. Serological tests are usually positive in the blood but may be negative in the CSF.

With adequate treatment the prognosis is generally good provided extensive cerebral infarction has not occurred. Serial transcranial Doppler studies have identified improved vascular flow after antibiotic treatment (Flint *et al.* 2005), with one case showing little resolution of stenotic vascular change at 4 months (Kelley *et al.* 2003). Sometimes the patient is left with fits, hydrocephalus or permanent intellectual impairment.

Tabes dorsalis

Tabes dorsalis is seen in conjunction with approximately 20% of cases of general paresis. Its highly characteristic signs and symptoms may therefore alert the psychiatrist to the latter disease. It is now an extremely rare presentation in the post-antibiotic era (Kinghorn 2000), with reported

evidence of a clear decline from pre-antibiotic cohorts (Wolters 1987).

Onset is usually 8–12 years after primary infection, although a range of 3–25 years is seen (Singh & Romanowski 1999). Males are affected much more frequently than females, with a peak age of onset in the fifth decade (Orban 1957). The essential pathology consists of degeneration of the ascending fibres from the dorsal root ganglia, resulting in atrophy of the dorsal roots and shrinkage and demyelination in the posterior columns of the cord together with dystrophic changes of optic nerve fibres and decreased neuronal numbers in brain, spinal cord and spinal ganglia.

Characteristic symptoms include pain, paraesthesiae and a marked disturbance of gait. These usually develop insidiously. The lightning pains of tabes are extraordinarily severe, can occur in 75–90% of patients and are typically brief and stabbing in nature and sharply localised in the legs. Burning and tearing pains may also occur, or girdle pains around the trunk. Paraesthesiae are also most common in the legs and feet; the skin may be hyperaesthetic to touch or the patient may feel he is walking on cotton wool. The ataxia is sensory in origin and due to loss of proprioceptive sensibility. The patient walks with a wide base or a typical ‘high stepping’ gait, and finds more difficulty in the dark when visual control is reduced. Romberg’s test is positive from an early stage.

Tabetic crises consist of episodic pain in the viscera. The gastric crisis is most common, with attacks of epigastric pain and vomiting. Laryngeal crises consist of dyspnoea, cough and stridor, rectal crises of tenesmus, and vesical crises of pain in the bladder and penis. Other manifestations are impotence and sphincter disturbances.

On examination, sensory changes are found earliest in the legs. Loss of postural sense and vibration sense are marked, and compression of the Achilles tendon may fail to produce pain. Other characteristic sites of sensory loss, involving both touch and pain, are the side of the nose, the ulnar aspect of the arms, patchy loss over the trunk and the dorsum of the feet. The musculature is hypotonic and the tendon reflexes diminished or absent, particularly at the ankles. The pupils are abnormal in 90% of cases, although the full spectrum of Argyll Robertson pupil (see General paresis/Abnormalities on examination, later) tends to be a late development. Ptosis and optic atrophy are frequently seen (Simon 1985). Painless disorganisation of joints may result in gross deformity (Charcot’s joints), most frequently at the knee or the hip. Perforating ulcers and other trophic skin changes may appear.

The CSF is usually under increased pressure, with a moderate number of mononuclear cells and a slightly raised protein. The Venereal Disease Research Laboratory (VDRL) test may be negative in both the blood and CSF in 20% of cases, and the fluorescent treponemal antibody absorption (FTA-ABS) test may be negative in the CSF despite an excess of cells and protein (Wiles 1993a).

Without treatment the disease is slowly progressive. General paresis may appear after a lapse of many years; even if it does not, long-standing cases may develop psychotic illnesses of a paranoid or depressive nature (Wilson 1940).

General paresis (dementia paralytica, general paralysis of the insane)

Hare (1959) has traced the fascinating history of this disease. It was first clearly described in the early nineteenth century by physicians working in the mental hospitals of Paris. It appears to have assumed epidemic proportions in France soon after the Napoleonic wars, and thereafter the spread by venereal infection can be traced along the trade routes of Europe and to the New World. Hare adduces detailed evidence to suggest that general paresis may have arisen as a new disease by mutation of the syphilitic spirochaete.

The disease occupies a unique place in several respects in the history of psychiatry. The final proof of its aetiology was an important landmark, likewise the discovery of its response to treatment. A relationship between syphilis and insanity had long been recognised, but there was much controversy before a syphilitic aetiology became accepted for general paresis. Hereditary taint, alcohol consumption, mental strain and even sexual excess were all championed as causes by various authorities despite the increasing epidemiological evidence that syphilis was responsible. The development of the Wassermann test in 1906 did not end the disputes, which persisted until Noguchi and Moore (1913) finally demonstrated *Treponema pallidum* in the brain itself. Thus a clear aetiology was eventually established for a mental disorder that was then extremely common.

Pathology

General paresis is the only syphilitic disease in which spirochaetes can be demonstrated in the tissues of the brain, and the pathology is thought to be the direct result of their action there. Macroscopically, the dura mater is thickened and opaque, and chronic subdural haemorrhage may contribute to the formation of a thick membrane over the brain (pachymeningitis haemorrhagica). The pia mater is firmly adherent to the underlying cortex. The brain itself is small and atrophied, with widening of the cerebral sulci and dilatation of the ventricles.

Microscopically, there are inflammatory lesions throughout the cortex, consisting of dense perivascular collections of lymphocytes and plasma cells and attributable to the irritation produced by the spirochaetes. Equally prominent are degenerative changes, with cortical thinning and outfall of neurones, especially in the frontal and parietal regions. Neuroglial proliferation is marked, forming a dense feltwork below the meninges and beneath the ventricular walls, the latter giving a ‘frosted’ granular appearance to the naked eye. Enlarged microglial cells (rod cells) are characteristi-

cally arranged in rows, and stain with Prussian blue to show iron-containing pigments in their cytoplasm. This reaction is held to be pathognomonic for general paresis.

The spinal cord may show secondary degeneration of the pyramidal tracts, or a combination of paretic and tabetic pathology with degeneration of the posterior columns.

Clinical features

In essence general paresis is a dementing process of insidious onset, but often coloured at first by other features that tend to obscure the intellectual impairment. Changes in affect or personality are frequently the presenting abnormalities as with Pick's disease (see Chapter 9); alternatively the dementing process may be concealed until some unexplained lapse of conduct brings the true situation abruptly to light. Thereafter the progress of the disorder is marked by certain characteristic features and by neurological disabilities that give the disease its name.

It is usual to describe several forms of general paresis according to salient aspects of the mental state. This remains useful in serving to underline the varied manifestations of the disease, although as indicated below the frequency of the different varieties has changed considerably, the disorder is rare and many atypical forms are now seen.

The disease affects males much more commonly than females, with a peak age of onset between 30 and 50 though the latitude is wide. Congenital general paresis can be declared in early childhood and cases are also seen in extreme old age. The time from infection is difficult to determine, but is usually quoted as being 5–25 years, with an average of 10–15 years.

Presenting features

In retrospect it is often discovered that the patient has experienced minor ill-defined symptoms such as headache, insomnia and lethargy for several months before more definite manifestations appear. Relatives commonly report an insidious change of temperament – moodiness, apathy or decreased emotional control. Other common early changes may suggest frontal lobe involvement by way of coarsening of behaviour and loss of refinement in the personality.

Episodic forgetfulness is usually the first cognitive change, followed by defective concentration, reduction of interests and mental and physical slowing in the manner typical of a dementing process. Difficulty with calculation is stressed as an early feature, also disturbances of speech and writing. Insight is impaired from an early stage.

In approximately 50% of patients the presentation is abrupt, with some striking incident that first brings the patient to medical attention (Dewhurst 1969). Sometimes it is a lapse of social conduct that reveals the true state of affairs: law-breaking, an outburst of violence or an episode of indecent exposure (Roberts & Emsley 1992). Foolish, eccentric or

reckless behaviour may be the opening sign, as seen in the following examples from Wilson (1940).

In one case the first whim was the purchase of a quantity of old silver for which payment could not be made; another patient rose in his stall at the theatre and threw sovereigns at a comedienne on the stage; a third ordered 700 hymn books for a hospital ward of 16 beds, and a ton of guano for the ward plants. Another wrote to the War Office demanding three Victoria Crosses which he considered he had won in fighting some 10 years before. At the outbreak of hostilities in August 1914, an incipient paralytic sent telegrams to all the crowned heads and rulers, proffering his services as peacemaker.

Alternatively, some organic feature may be abruptly declared, such as an episode of amnesia, a single epileptic fit or status epilepticus (Ances *et al.* 2004), or an acute delirious episode. In Dewhurst's (1969) series, 5 of 91 cases presented with attempted suicide.

Grandiose or expansive form

This was by far the most frequent type of general paresis when the condition was first described, and it has tended to remain the prototype of the disorder in medical teaching. However, there is evidence that it had already become less common in Europe during the latter half of the nineteenth century and perhaps somewhat later in England (Hare 1959). Nowadays it is comparatively rare. In large series of cases from England, America and Norway it has represented only 10%, 18% and 7% of cases, respectively (Frøshaug & Ytrehus 1956; Hahn *et al.* 1959; Dewhurst 1969). How far the change over time has depended on alterations in the host, the infecting organism or cultural factors is unknown. In some countries the proportion apparently continued to be high, for example in India (Varma 1952) and China (Liu 1960), when it had already become rare elsewhere.

Florid examples are certainly impressive and share symptoms of mania (Hoffman 1982), which may lead to their being highlighted in reports of the disease. The hallmark is the patient's bombastic and expansive demeanour, with delusions of power, wealth or social position. The patient boasts of fantastic riches, exploits in battle, or tells of his athletic and sexual prowess. He may believe he is some eminent person from the past or present, yet at the same time accepts his stay in hospital without complaint.

The mood is euphoric and frequently condescending. The patient's recital may be amusing but his jocularly is rarely infectious, the underlying dementia imparting a shallowness to the prevailing affect. If his beliefs are questioned, the mood may readily turn to petulance or anger.

With arrest of the disease the clinical picture can remain remarkably static over many years. Formerly the delusions tended to die out with progression of the disease, and expansiveness gave way to apathy, lethargy and indifference.

Simple dementing form

This appears over time to have gradually replaced the grandiose form and is now a great deal more common. It represented 20% in Dewhurst's (1969) series, 60% in Hahn *et al.*'s (1959) series and 48% in Frøshaug and Ytrehus' (1956) series. The usual symptoms of generalised dementia are in evidence, with impairment of memory, slowed and laboured thinking and early loss of insight. Progress may be punctuated by transient episodes of impairment of consciousness during which behaviour becomes even more confused. The affect is shallow; a mild euphoria is common, although many patients are dull and apathetic from the start. As with other dementing illnesses the patient may develop fleeting and ill-systematised delusions, mostly of a persecutory nature. Generally, however, such patients are quiet, lethargic and amenable throughout the course of the disease.

Depressive form

This important variety appears also to have increased considerably at the expense of the grandiose form. It emerged as the commonest variety (27%) in Dewhurst's (1969) series. The patient presents with classic symptoms of a depressive illness. If dementia is already advanced, it may be noted that the affect is somewhat shallow and that the patient is more readily lifted from his gloom than in primary affective disorders. Sometimes, however, no such distinction can be made. Delusions are of a typically melancholic kind; nihilistic and hypochondriacal delusions may be grotesque in degree, though again the mood may be noted to be disproportionately shallow.

Taboparetic form

In perhaps 20% of patients the picture of general paresis and tabes dorsalis are combined. Along with dementia the classic tabetic symptoms and signs (see Tabes dorsalis in this chapter) are observed. The mental symptoms are then often rather mild. True Argyll Robertson pupils and optic atrophy are seen more commonly in this variety than with general paresis alone.

Other forms

Other forms of the disorder are much less common. There may occasionally be a picture of true manic elation accompanied by flight of ideas, or a presentation with schizophrenic features that mask the true diagnosis. Paranoid delusions are then common, together with ideas of influence, passivity phenomena and auditory hallucinations of an abusing or threatening nature ('paranoid' or 'paraphrenic' form). In the

'neurasthenic' form the outstanding features are weakness, fatigue, irritability and complaints of general ill health. Presentation with an acute organic reaction represents an active and rapidly progressive form of the disease. Very occasionally this follows a fulminating course with fever, fits and a picture simulating encephalitis. Cases have been reported which for some time preserve the appearance of Korsakoff's psychosis (Wilson 1940). An epileptic or apoplectic presentation occurred in 15% of Frøshaug and Ytrehus' (1956) series and in 8.7% of Timmermans and Carrs' (2004) series. In Lissauer's type, the patient presents with hemiparesis, aphasia or other evidence of focal brain disease as a result of massive localised brain destruction. The common presentation nowadays, with a markedly attenuated picture.

Juvenile general paresis

This has always been extremely rare and is now hardly ever seen. Infection is transmitted via the placenta and the disease is declared in childhood or adolescence. The usual age of onset is between 6 and 21 years. Onset in childhood leads to learning difficulties at school and results in symptoms of mental impairment. Epileptic fits are common. Onset in adolescence leads usually to the simple dementing type of general paresis. The same neurological and CSF abnormalities are seen as in the adult form of the disease.

Abnormalities on examination

The patient frequently shows evidence of poor physical health. In the mental state there will usually be evidence of some degree of dementia if full attention is paid to the assessment of recent memory and other cognitive functions. However, this may require considerable persistence in the face of facile excuses and evasive behaviour. Confirmatory signs may be found on neurological examination even in the absence of definite organic features in the mental state. Pupillary abnormalities, tremor and dysarthria head the list of abnormal findings.

The pupils show abnormalities in about two-thirds of cases. A variety of changes is seen: inequality, irregularity and sluggishness of reactions. The full syndrome of Argyll Robertson pupil may be present but not so commonly: a small pupil, irregular in outline and with atrophy of the iris, which reacts normally to convergence but not at all to light, and does not dilate fully under the influence of a mydriatic. Optic atrophy may be in evidence even when the patient has no complaint of visual impairment.

Tremor also occurs in about two-thirds of patients when first seen. It typically involves the face and hands particularly. Close attention may be required to detect it in the lips and around the mouth. Tremor of the hands and fingers contributes to the clumsiness seen on manual tasks.

Dysarthria is partly due to the tremor of the lips and tongue. Speech becomes slurred, hesitant and jerky, and the voice feeble and lacking in intonation. Dysphasic difficulties may also be found.

Reflex abnormalities consist of exaggeration of the knee and ankle jerks, with clonus and spasticity in the lower limbs. With progression of the disease the plantar responses become extensor, and there is increasing weakness of the limbs leading eventually to severe spastic paralysis. In contrast, tendon reflexes may be absent when tabes dorsalis is combined with general paresis.

Incoordination is seen in the clumsiness of the hands and the characteristic slouching, unsteady gait. In taboparesis it becomes a marked feature, with Rombergism and the classic high-stepping gait.

Further progress

In the absence of treatment the dementia increases steadily along with marked physical deterioration. Periods of arrest or even complete remission were occasionally seen, but usually only for a few weeks or months at a time. Incontinence of urine appears early. Delusions gradually fade away with the other more florid mental features, and the patient becomes quiet, incoherent and apathetic. The characteristic picture in the later stages was of a childish gentle personality, seldom aggressive and with much of the dementia concealed beneath good-tempered polite behaviour (Storm-Mathisen 1969). Spastic paralysis and ataxia increased until the patient was enfeebled and confined to bed. Epileptic attacks, both grand mal and psychomotor, occurred in approximately half of the cases, and the progression of neurological disabilities was often speeded by the appearance of 'congestive attacks'. These consist of sudden episodes of loss of consciousness, hemiplegia, monoplegia, aphasia or hemianopia, lasting a few days or weeks at a time but eventually leaving enduring deficits in their wake. The mechanism responsible remains uncertain but a vascular basis is probable. Death usually occurred within 4–5 years of presentation. This uniformly disastrous prognosis has, of course, been dramatically altered by present methods of treatment as described below.

Atypical present-day forms of neurosyphilis

In addition to the risk of overlooking the disease on account of its rarity, we nowadays face the additional problem that neurosyphilis can occur in atypical or attenuated forms in the post-antibiotic era, as well as comorbidly with HIV. Thus while fully developed examples of general paresis and tabes dorsalis have become less often reported, modified forms of neurosyphilis with atypical presentations and relatively minor symptomatology are increasingly encountered (Anon.

1978). In Hooshmand *et al.*'s (1972) series of 241 patients in the USA, almost half presented with unrelated symptoms, the diagnosis being made by routine investigation after suspicion had been aroused by neurological or ocular findings. In one-quarter the presentation was with focal or generalised seizures (see also Luxon *et al.* 1979). Wolters (1987) compared cases from the pre- and post-antibiotic era and did not identify any significant between-group difference, other than a decline in diagnoses of tabes dorsalis. This finding was corroborated in a 1990–1999 cohort of 161 South African patients where the clinical presentations were identical to those seen prior to antibiotics (Timmermans & Carr 2004). However, the authors noted that the cohort population had poor access to health care and had likely been less exposed to equivalent quantities of antibiotics than their counterparts in Western societies (Timmermans & Carr 2004). Similar conclusions have been reached in other studies (Conde-Sendin *et al.* 2004; Delli *et al.* 2007).

In atypical cases little may appear to be pathognomonic, either in the clinical picture or on CSF examination. Hooshmand *et al.*'s (1972) criteria for the diagnosis of neurosyphilis are therefore important. They recommend a firm diagnosis when (i) the blood FTA-ABS test (see below) is positive and there are ocular or neurological findings suggestive of neurosyphilis; (ii) the FTA-ABS test is positive in both blood and CSF and the latter contains over 5 leucocytes/mm³ in the absence of bacterial or viral meningitis; or (iii) when blood and CSF FTA-ABS tests are positive in the presence of progressive neurological symptoms not otherwise explained. In the last category there must also be either a transient leucocytosis in the CSF after administering penicillin, or the patient must improve clinically on penicillin. A positive FTA-ABS test in the blood and CSF as the sole abnormal finding may not necessarily imply active neurosyphilis, since this can have persisted as a serological finding after adequate antibiotic treatment. Subsequently, case definition criteria have also been established for the diagnosis of neurosyphilis by the CDC in 1996 (Box 7.4).

Neurosyphilis and HIV coinfection

The risk factors for acquiring syphilis are similar to those for the transmission of HIV (Zellán & Augenbraun 2004). After an initial decline in the incidence of syphilis, associated with the beginning of the HIV pandemic in the 1980s and contingent changes in sexual practice, there has been an increasing number of reported coinfections that, alarmingly, may be associated with increasingly unsafe behaviours (Buchacz *et al.* 2005). Another important factor affecting the prevalence of coinfection is the increased life expectancy associated with HAART (Fenton & Imrie 2005). The transmission of both HIV and syphilis is reciprocally potentiated, particularly through genital ulceration (Douglas *et al.* 2005) and the

Box 7.4 Criteria for diagnosis of neurosyphilis*Clinical presentation*

Evidence of CNS infection with *T. pallidum*

Laboratory criteria

Reactive serological test for syphilis and reactive VDRL in CSF

Probable case

Syphilis of any stage, a negative VDRL in CSF, and both the following.

- Elevated CSF protein or leucocyte count in the absence of other known causes of these abnormalities
- Clinical symptoms or signs consistent with neurosyphilis without other known causes for these clinical abnormalities

Confirmed case

Syphilis of any stage that meets the laboratory criteria for neurosyphilis

effects on HIV viral load and CD4 counts by syphilis (see Buchacz *et al.* 2004).

The hypothesis that atypical and attenuated presentations of neurosyphilis in immunocompetent individuals are likely associated with incomplete or ineffective antibiotic therapy has already been suggested. Similarly, changes in the presentation and natural history of neurosyphilis, despite usually adequate treatment, are associated with comorbid disorders that affect the patient's immune response, particularly HIV.

More recent epidemics of infectious syphilis have particularly involved the population of men who have sex with men (see Acquired immunodeficiency syndrome, later). Not surprisingly, presentations of neurosyphilis have similarly been increasingly reported in this group and particularly in those who are HIV seropositive (Musher 1991) some of whom have a rapid progression to neurosyphilis, with or without treatment (Johns *et al.* 1987). The CDC conducted a review of such cases across four cities in the USA in order to describe the clinical course of early symptomatic neurosyphilis in men who have sex with men, particularly HIV-positive individuals (Centers for Disease Control 2007). This found that the estimated risk of having symptomatic early neurosyphilis in this group was 1.7%, with 0.5% having persistent symptoms 6 months after treatment. Of the cases, 75% had presented with visual disturbance or new-onset headache, 12% with acute meningitis and 50% with no other signs or symptoms of syphilis whatsoever. Of concern, 25% had been undiagnosed with HIV.

Investigations

The UK Public Health Laboratory has produced guidelines that identify the most appropriate investigations for syphilis

(Egglestone & Turner 2000). They indicate that serological tests for syphilis can be divided into two groups.

1 Non-treponemal tests: the VDRL test and rapid plasma reagin (RPR) test detect non-specific treponemal antigens utilising a modified Wassermann reaction.

2 Treponemal tests: *Treponema pallidum* haemagglutination assay (TPHA), FTA-ABS and most enzyme immunoassay (EIAs).

Investigations such as the Wassermann reaction and other non-treponemal tests such as the VDRL are positive in the blood in 90% or more of untreated cases of general paresis, but this figure may be considerably lower if antibiotics have been given for some other infection or if a previous course of treatment has been carried out. They may also be negative in patients with HIV. False positives may be obtained in certain diseases, notably leprosy, systemic lupus erythematosus, thyroiditis, haemolytic anaemia and some cases of rheumatoid arthritis. The tests may also be positive for a while after some viral infections, after vaccination, during pregnancy and in an appreciable proportion of drug addicts. The cardiolipin Wassermann reaction uses a purer antigen and gives fewer false positives in these situations. The Reiter protein complement fixation (RPCF) test operates on spirochaetal material from non-pathogenic treponemes, and is therefore negative in the above diseases but may be positive in other spirochaetal infections such as yaws.

Positive results from the Wassermann reaction or VDRL, along with a positive RPCF test, means that the possibility of syphilitic infection is high. More certainty will be given in marginal cases by treponemal tests such as *Treponema immobilisation* (TPI), TPHA or FTA-ABS. The TPI test is reasonably specific to *T. pallidum* but is technically difficult to perform and not recommended in the guidelines. The TPHA test uses an indirect haemagglutination technique, yielding a high degree of specificity and lending itself to automated methods. Development of the FTA test marked an important advance, particularly in the form of an absorption test (FTA-ABS). This is generally very reliable, although false positives occasionally occur with sera containing antinuclear/rheumatoid factor or possibly because of passive diffusion of treponemal antibodies from the blood into CSF. True positive results are obtained with yaws. Negative results are occasionally seen in patients who are HIV positive. The FTA-ABS test is fortunately almost invariably positive, in both the CSF and the blood, in the modified forms of neurosyphilis encountered in present-day practice (Oates 1979). For many years the combination of VDRL and TPHA was favoured in UK laboratories. However, difficulties with automating these investigations has resulted in increasing use of EIAs that detect treponemal IgG or IgG and IgM. Treponemal IgM remains detectable in treated late disease for up to 18 months, but is usually undetectable after 3–9 months in early treated cases. Confirmatory testing with TPHA is recommended after a reactive EIA.

The possibility of negative results with certain serological tests in the blood means that the CSF must be examined in every case when the presence of neurosyphilis is even remotely suspected. Such tests are positive in the CSF in almost every untreated case of general paresis, although the VDRL may be negative in a considerable proportion (Davis & Schmitt 1989; Lee & Chen 2005). CSF FTA-ABS is a highly sensitive but poorly specific treponemal test. At lumbar puncture the pressure is often raised, there is a moderate lymphocytosis of 5–50 cells/mm³, and the protein is also usually elevated (50–100 mg/dL). The globulin ratio is greatly increased and oligoclonal bands may be present. There is generally little correlation between the initial CSF cell or protein level and the severity of the clinical picture. A CSF without raised cells or protein may be seen if there has been previous treatment. A recent study reported that those with increased CSF tau protein were statistically more likely to have CNS involvement and therefore the measurement of CSF tau protein might be used in discriminating between syphilis with and without CNS involvement (Paraskevas *et al.* 2007).

In the great majority of patients with general paresis EEG is abnormal, with an excess of theta and slower wave activity.

Differential diagnosis

The forms of neurosyphilis are so variable in presentation that serological tests should be considered in all patients admitted to psychiatric units. In the outpatient clinic there must be a readiness to perform such tests when the index of suspicion is high. Roberts and Emsley (1992) reported 21 patients admitted to acute psychiatric units with neurosyphilis, in only three of whom the diagnosis had been considered before the results of routine serology were known. The initial diagnoses had encompassed schizophrenia, depression, mania and hysteria, in addition to delirium and dementia. Cleare *et al.* (1993) found a continuing low prevalence of positive serology (at almost 4%) among psychogeriatric inpatients, this not infrequently reflecting active disease. Other examples where mistakes were averted are reported by Sirota *et al.* (1989) and Sivakumar and Okocha (1992). At the very minimum the pupil reactions and tendon reflexes should be examined at every new consultation. However, clinical examination without serology is not always enough to avoid errors in diagnosis; this was illustrated by Steel (1960) in patients in a psychiatric observation ward and by Joffe *et al.* (1968) in patients seen in a neurological clinic. The present-day frequency of attenuated forms and atypical presentations, as well as the prevalence of comorbidity with HIV and the detrimental effects of this, make the application of routine serology very much more important.

Boyle *et al.* (1995) report the history of a 62-year-old man who presented with expressive dysphasia, anxiety and agitation in the context of his wife's hospitalisation with probable prion disease. There were no abnormalities on examination and initial investigations other than serum glucose were normal, including chest radiography and ECG. An initial diagnosis of dissociative disorder was made and the opinion of a psychiatrist sought. Cognitive testing later in his admission identified significant impairment, with a Mini-Mental State Examination (MMSE) score of 18/30. CT identified advanced cerebral atrophy. EEG revealed excessive temporal and anterior slow waves. Features of the mental state at this stage included confabulation, perseveration, social disinhibition and grandiosity. VDRL, TPHA and FTA tests were positive. CSF was VDRL and FTA positive. A diagnosis of neurosyphilis was made.

A history of change of personality, impaired emotional control and intellectual decline will immediately suggest general paresis, and the presence of tremor, dysarthria or pupillary or reflex abnormalities will almost suffice to confirm the diagnosis. However, such well-established cases are nowadays rare at the time of initial presentation. In Dewhurst's (1969) series only 24 of 91 cases were diagnosed as having neurosyphilis from the outset. The most common initial diagnoses were depressive illness, dementia, confusional states, schizophrenia, hypomania and epilepsy.

General paresis must obviously be considered in all patients who present with organic impairment of intellect, and no patient should be diagnosed as suffering from a primary dementia until syphilis has been excluded. Among older arteriopathic patients mistakes are particularly likely to be made, since tremor and dysarthria are then not entirely unexpected. However, pupillary abnormalities are rarely seen in cerebral arteriosclerosis or other dementing illnesses.

Affective psychoses appear to have been closely simulated in many of Dewhurst's patients. On occasion the clinical picture may also be typical of schizophrenia, to the extent that the CSF findings come as a surprise (Frøshaug & Ytrehus 1956). Where routine serological testing is not possible the principal safeguard must lie in careful and systematic examination of the nervous system, and due attention to any organic mental impairments which emerge.

There is a special risk of overlooking the diagnosis in alcohol-dependent patients. Emotional instability or expansiveness may be attributed to alcoholic deterioration, likewise social lapses, facile behaviour, tremulousness and dysarthria.

General paresis may be confused with cerebral tumour when headache is marked and the personality attributes of

frontal lobe damage conspicuous. An anterior basal meningioma may mimic the disease closely when compression of the optic pathways leads to pupillary changes and optic atrophy.

General paresis must also be borne in mind in the differential diagnosis of epilepsy of late onset, and in all acute organic reactions when other causes are not immediately obvious.

Finally it is necessary to distinguish between general paresis and other neurosyphilitic diseases, in particular chronic meningovascular syphilis and asymptomatic neurosyphilis. In chronic meningovascular syphilis the prognosis is much better than in general paresis. Meningovascular syphilis tends to occur earlier than general paresis, shows a more acute development, and fluctuations in its course are usually marked. Insight is generally better preserved, the personality less deteriorated and focal neurological signs somewhat more common.

Treatment

Adequate treatment of syphilis in the primary stage prevents the development of general paresis later. Similarly, energetic treatment must be pursued, essentially as for general paresis, in those cases of 'asymptomatic neurosyphilis' where lumbar puncture reveals abnormalities in the CSF before any clinical signs or symptoms of nervous system involvement have become apparent. For this reason routine lumbar puncture is often advocated in every case of primary syphilis, and yearly examination of the CSF in those who show abnormalities in the early stages. In patients who are HIV positive it is generally agreed that treatment should be as for general paresis, even for those in the primary or secondary stages (Nieman 1991). On the whole, treatment of people infected with HIV is the same as those who are HIV seronegative.

Penicillin therapy

For the treatment of established general paresis, penicillin alone is generally agreed to be adequate and can eliminate syphilitic infection in the brain in the great majority of cases. Benzylpenicillin is the preparation of choice and must be given by intramuscular injection; as procaine benzylpenicillin it can be given by daily injections. However, benzathine benzylpenicillin, given as a single injection per week, will not suffice. This regimen appears to be effective for the treatment of primary syphilis in patients who are likely to be uncooperative over daily attendance, but there is now evidence that it yields inadequate CSF levels for the treatment of neurosyphilis (Mohr *et al.* 1976; Tramont 1976). The minimum effective dose has not been established with certainty, but aqueous benzylpenicillin 18–24 million units i.v. daily for 10–14 days is the current preferred guideline (Greenwood 1996; Centers for Disease Control 2006b).

A Herxheimer reaction is liable to occur in 5–10% of cases within the first few days of treatment. Because of this, these

days of treatment are best undertaken in hospital. The reaction may consist of malaise and fever alone or result in exacerbation of symptoms, sometimes with seizures. Oral prednisone given the day before and during the first few days of treatment helps to prevent its occurrence. When sensitivity to penicillin precludes its use it may be necessary to substitute ceftriaxone 2 g parenterally for 10–14 days (CDC 2006). Chloramphenicol and doxycycline have been shown to achieve adequate penetration of the CSF and are options, although with limited data to support them. Where patients are penicillin sensitive, consideration should be given to penicillin desensitisation procedures (Arroliga & Pien 2003). Fortunately, spirochaetal resistance to penicillin does not appear to have developed; all early syphilis continues to respond and it is unlikely that other antibiotics confer extra benefit.

Other treatment

Antipsychotic drugs are indicated for the control of excitement, agitation or florid delusions or hallucinations as in any other psychotic illness and there are case reports of the use of atypicals being effective (Taycan *et al.* 2006), similarly antidepressant drugs for severe depressive symptoms. Anticonvulsants are required for the symptomatic treatment of epilepsy. It must be borne in mind that a small proportion of cases may represent a coincidence between asymptomatic neurosyphilis and an independent psychotic illness, and the latter will then warrant full psychiatric management in its own right.

There is some evidence to contraindicate the use of electroconvulsive therapy in general paresis, particularly in the presence of active disease as mirrored in the CSF. Sudden worsening with focal signs of neurological defect has been reported to follow electroconvulsive therapy in such cases, and Dewhurst (1969) provides data that suggest the possibility of an impaired overall prognosis.

The complete care of the patient will include planned rehabilitation when deficits persist, in the knowledge that they may show continued slow improvement for up to 2 years following arrest of the disease. From the outset it is necessary to make every effort to test the blood serology of the patient's partner and any children.

Follow-up and retreatment

Patients should be followed up both clinically and serologically after treatment, depending on disease stage and HIV status. It has been recommended that in neurosyphilis, CSF analysis should be repeated every 6 months until the cell count is normal. Inadequate treatment has been defined as failure of the CSF to normalise within a 2-year period or cell count not having decreased within 6 months. Follow-up in those who are coinfecting with HIV should be aggressive. If abnormalities in cells or protein persist, a second course should be given immediately. Failure to show clinical

improvement does not automatically warrant retreatment if the CSF has shown an entirely satisfactory response. In this situation the essential step is re-evaluation of the diagnosis, since syphilitic infection may have been coincidental with other disease.

The first sign of relapse is seen in the CSF cell count; if this rises above 5 cells/mm³ at any follow-up examination, retreatment is strongly indicated. A persistently elevated protein is not of the same significance, and can usually be disregarded if cell counts remain low and there is no clinical evidence of progression. Serological tests may remain positive in the blood and the CSF for several years after resolution of all active infection. However, rising titres in the blood serology should cause concern and may point to continuing activity or reinfection. This will always indicate the need for re-examination of the CSF at any point during the follow-up period.

Clinical evidence of progression of the disease will always raise the possibility of the need for retreatment, especially when the initial response was good. However, routine retreatment confers no additional benefit.

Outcome of treatment

The outcome that can be expected was comprehensively described by Hahn *et al.* (1959) from a multicentre follow-up study of 1086 patients in the USA. Their general conclusion is of great importance, namely that success depends essentially on early diagnosis and prompt administration of a fully adequate course of treatment.

Of mild or early cases, 80% obtained clinical remission and proved capable of resuming work. In this group there were hardly any deaths from paresis. The prognosis for ability to work and to live in the community was directly proportional to the severity of the illness and the duration of decreased work capacity at the time of treatment. However, even severely affected institutionalised patients were still capable of considerable benefit, and stood a one in three chance of improving sufficiently for rehabilitation and ultimate return to work. Certain symptoms were associated with a poor overall prognosis, including incontinence, inability to dress and neglect of personal hygiene. In patients over 60 years old, remission or improvement became much less frequent, probably because of the presence of cerebrovascular changes.

Interesting correlations were found in relation to the CSF abnormalities at the time of treatment. The more active the fluid in terms of cell count, the greater the chance of a good clinical response; at the same time, however, the likelihood of clinical progression was then also increased in certain cases. This apparent paradox is explained by the fact that pleocytosis in the CSF reflects an active and labile process, whereas an inactive fluid indicates a relatively static pathology. The latter is less susceptible to treatment but also less likely to result in clinical progression.

The quality of recovery extended to a wide range of organic mental symptoms and florid psychotic phenomena. At 5-year follow-up, the following symptoms and signs had resolved completely in over half of the patients who showed them: disorientation, convulsions, tremors, incontinence, euphoria and depression. In over one-quarter there was resolution of impaired memory, judgement, insight, speech, calculation, delusions and hallucinations. Clearly there is considerable leeway for restoration of function in favourable cases, although with long-established disease one can hope merely to halt progression of the disorder. The overall death rate 10 years after treatment was 31%, 9% being attributable to general paresis and a further 22% to other causes. Altogether this was almost four times the death rate to be expected for non-syphilitic patients of a similar age.

Currie *et al.* (1988) also identified that clinical improvement was associated with decreasing CSF pleocytosis rather than with a decline in protein levels. Wilner and Brody (1968), in a prolonged follow-up of 100 patients, showed that new neurological manifestations were liable to develop in some 30% of cases, consisting of grand mal epilepsy, paraplegia, hemiparesis, optic atrophy or oculomotor palsies. These occurred even among patients who had been treated with penicillin, the average interval between treatment and such developments being 12 years. However, it was uncertain whether this always represented progression of the neurosyphilis rather than increased susceptibility to other neurological disease, and penicillin may often have been given in inadequate dosage. Roberts and Emsley (1995) in a case series of 12 patients identified a negative correlation between 1-year improvements in MMSE scores and CSF VDRL titres and suggested that this may be an early indicator of continued disease activity, even in the absence of declared neurosyphilitic symptoms.

Encephalitis

Encephalitis refers to a primary disease in which viral agents cause inflammation of the brain. Meningoencephalitis is the more appropriate term when a marked element of meningeal irritation exists as well. Virological studies have gone some way towards isolating and demonstrating the responsible organisms, especially in large epidemics, but a large number of cases remain in which a viral aetiology is merely presumed to operate on account of the general features of the illness. This applies particularly to sporadic cases where opportunities for extensive virological investigations may not be available, but is also true of some large epidemics, notably of encephalitis lethargica in which a specific agent was never conclusively demonstrated.

In some cases of known viral infection it is uncertain whether the virus actually gains access to the CNS or whether the central nervous changes represent an autoimmune or hypersensitivity reaction to the presence of viral infection

Table 7.2 Causes of acute viral encephalitis (rarer or suspected arboviral causes are shown in parentheses). (From Solomon *et al.* 2007.)

<i>Non-geographically restricted sporadic causes</i>
Herpesviruses: herpes simplex virus types 1 and 2, varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, human herpesvirus types 6 and 7
Enteroviruses: coxsackieviruses, echoviruses, enteroviruses 70 and 71, parechovirus, poliovirus
Paramyxoviruses: measles virus, mumps virus
Others (rarer causes): influenza viruses, adenovirus, parvovirus, lymphocytic choriomeningitis virus, rubella virus
<i>Geographically restricted causes (mostly arthropod-borne*)</i>
The Americas: West Nile, La Cross, St Louis, Rocio and Powassan encephalitis; Venezuelan, eastern and western equine encephalitis; Colorado tick fever virus, dengue virus and rabies virus
Europe/Middle East: tick-borne encephalitis, West Nile, Toscana, rabies (dengue virus, louping ill virus)
Africa: West Nile (Rift Valley fever virus, Crimean-Congo haemorrhagic fever, dengue, chikungunya), rabies
Asia: Japanese encephalitis, West Nile, dengue, Murray Valley encephalitis, rabies (chikungunya virus, Nipah)
Australasia: Murray Valley encephalitis, Japanese encephalitis (kunjil, dengue)

* All are arthropod-borne, except for rabies and Nipah virus.

elsewhere in the body. The latter is thought to be the principal mechanism in many of the forms of encephalitis that follow childhood infectious diseases.

It is now also apparent that viruses play a part in some subacute degenerative diseases of the brain, for example the measles virus in subacute sclerosing panencephalitis (see Encephalitis, later) and the JC polyomavirus in PML (see Acquired immunodeficiency syndrome, earlier). Direct infection of the brain with HIV-1 appears to be central to the development of HAD (see HIV-associated cognitive disorders, earlier). A comprehensive classification of encephalitis is difficult, but Table 7.2 delineates the main categories for discussion (Solomon *et al.* 2007).

The relative incidence of the different forms has been demonstrated in a study from Finland that employed PCR to identify the virus present in CSF in some 3000 cases of CNS infection (Koskiniemi *et al.* 2001). Surprisingly, and against conventional wisdom, VZV was most frequently detected (29%). HSV and enteroviruses each accounted for the aetiology in 11% and influenza A virus in 7%. However, the cause remained uncertain in the remainder. This is a common finding, with between 50% and as many as 85% of cases remaining with an unknown cause in a variety of studies.

The worldwide incidence of acute encephalitis is variable but is thought to be 3.5–7.4 per 100 000 patient-years. HSV is generally reported as the most common sporadic cause in the Western world, with an annual incidence between 1 in 250 000 and 1 in 1 000 000 persons (Granerod & Crowcroft

2007), although this may be an underestimate (Kennedy 2005).

Sejvar (2006) has identified the evolving epidemiology of viral encephalitis with particular attention to the spread of the arbovirus West Nile virus in North America. This, along with Japanese encephalitis virus, is notably thriving in new areas (Solomon & Winter 2004). There have been West Nile outbreaks in the Americas and southern Europe and the virus has also been identified in the UK, although there have not been human cases reported as yet (Buckley *et al.* 2006; Morgan 2006).

Human immunodeficiency virus and other causes of immunocompromise including transplant surgery and chemotherapy have also changed the epidemiology of encephalitis, with CMV, EBV and human herpesvirus 6 presenting more commonly in this context (Solomon *et al.* 2007).

Clinical presentation

The characteristic clinical presentation in most forms of acute encephalitis is of a flu-like prodrome rapidly developing into an illness with headache, fever, nausea and vomiting, irritability and photophobia. Virus-specific clinical features that may present are highlighted later in the discussion. Some degree of neck stiffness is often detectable, and papilloedema may develop due to cerebral oedema. The pyrexia can be variable, low grade and easily overlooked. Equally, in a study by Raschilas *et al.* (2002), 91% of adults, later diagnosed with HSV-1 encephalitis, presented with high fever on admission.

The principal feature of cerebral involvement is disturbance of consciousness, ranging from mild somnolence to coma. Delirium features prominently in some varieties and disorientation (76%) and behavioural change (41%) were prominent in Raschilas *et al.*'s cohort. Seizures are common, especially in children, and can be the opening presentation of the illness. Focal neurological signs vary greatly according to the site of major impact of the inflammatory process, and are sometimes remarkably slight or even totally absent. Among the most common are pupillary changes, ocular palsies, nystagmus, ataxia, or disturbance of the long tracts with alteration of tendon reflexes, upgoing plantar responses and pareses of the limbs. Symptoms of temporal lobe involvement such as aphasia and dysphasia strongly suggest HSV infection. Sometimes the spinal cord is involved, with retention of urine or paraparesis.

Special interest attaches to cases that present with psychiatric disorder and cases have been included to illustrate this where possible. Mental disorder was recognised in the early epidemics of encephalitis lethargica (see Encephalitis lethargica, later), which will be discussed in detail, but examples still occur with other varieties. It has been suggested that the long-term psychiatric sequelae are considerable, but there is a need for further standardised clinical investigation (Arciniegas & Anderson 2004). As an indicator of psychiatric mor-

bility, Dowell *et al.* (2000) report that respondents to an Encephalitis Society questionnaire on their current state of functioning identified frustration and anger (68%), anxiety (67%), mood swings (59%) and depression (58%).

Caroff *et al.* (2001) reviewed 62 cases of encephalitis and identified the initial presenting symptoms to be delusions (54%, predominantly persecutory and nihilistic), hallucinations (auditory 44%, visual 13%, olfactory 3%, gustatory 1%) and affective disorder (depression 21%, euphoria 6%). Sometimes impairment of consciousness and neurological signs are absent at the time of presentation, as in the three patients reported by Misra and Hay (1971) who were admitted to a psychiatric unit with a provisional diagnosis of schizophrenia. Virological studies were apparently not performed.

A boy of 18 was admitted with a 2-day history of odd behaviour. He was excited, overactive and aggressive, with thought disorder and catatonic features. Two days after admission one plantar response was equivocal, and 2 days later both plantars were extensor and the left abdominal reflexes diminished. Lumbar puncture revealed no abnormality. He became pyrexial and developed subacute delirium. EEG showed a reduction in alpha rhythm and generalised slow activity. He was treated with corticotrophin. Subsequently he developed postencephalitic parkinsonism.

A woman of 45 was admitted with a 3-week history of depression and irritability and a 2-week history of paranoid delusions. On examination she admitted to thought withdrawal and auditory hallucinations. Three days after admission she became pyrexial and an extensor plantar response was elicited. Lumbar puncture was normal but EEG showed a general excess of symmetrical fast activity. She developed atrial fibrillation and congestive heart failure. She was treated for encephalitis and myocarditis and eventually made a complete recovery.

Wilson (1976) presented further striking cases of this nature, showing abrupt onset of psychological disturbance and little by way of neurological dysfunction in the early stages. Crow (1978) reviews other scattered examples that illustrate the potential overlap with schizophrenia. The majority probably represent cases of HSV encephalitis (see Non-geographically restricted sporadic encephalitides in this chapter).

The course of illness can vary greatly from one patient to another, and from time to time in a single patient, no matter what the causative organism. Profound coma may improve dramatically after some days or weeks, or unexpected relapse may follow steady recovery. When the acute phase is over

there is generally a long period of physical and mental recuperation that may continue for several months. Occasionally, the acute phase is succeeded by a prolonged phase of disturbed behaviour, which may outlast all evidence of active infection and closely simulate a psychogenic reaction.

Geographically restricted encephalitides

This group contains illnesses that occur in epidemics in different parts of the world and are transmitted to humans through animal or insect vectors. The majority of viruses are arthropod-borne, i.e. the vector is an infected insect, chiefly the mosquito, although in some cases ticks and mites are involved. In the Americas the main varieties are West Nile, La Crosse, Rocio and Powassan encephalitis; Venezuelan, eastern and western equine encephalitis; and Colorado tick fever, dengue and St Louis encephalitis, distinguished mainly by their geographical locations (Solomon *et al.* 2007). Louping ill is the only member of the group seen in England in humans and this is very rare. It is derived from sheep via sheep ticks. There are more reports of this virus in Europe, alongside presentations with tick-borne encephalitis (Charrel *et al.* 2004). Japanese B encephalitis virus is the main cause of viral encephalitis in Asia (Diagana *et al.* 2007) and became well known to the Western world by affecting troops in the Far East during the Second World War. It can present with acute flaccid paralysis in contrast to the usual encephalitic presentation (Chung *et al.* 2007) and is associated with psychiatric presentations including social inappropriateness, aggression, emotional lability, and affective and paranoid symptoms (Monnet 2003).

Transmission patterns of arthropod-borne viruses are often linked to the migration of birds, although changes in geographical distributions may also be seen with future climate change, potentially allowing agents such as West Nile virus, whose mosquito vector is present in the UK but dormant because of the colder climate (Morgan 2006), to flourish. West Nile virus like Japanese B encephalitis virus can also present with flaccid paralysis, as well as parkinsonism and myoclonus (Davis *et al.* 2006; DeBiasi & Tyler 2006).

Recurrent epidemics are a feature of all the diseases listed, often with a seasonal incidence in the warm summer months, and varying somewhat in virulence from one epidemic to another. In some epidemics overt disease is rare in comparison to the number of abortive cases who are found to harbour the viruses without showing signs of illness. This naturally leads to considerable difficulty in reaching a satisfactory laboratory confirmation of the disease when sporadic cases arise, although rising titres of antibodies on repeat examination may help.

Rabies

Rabies is transmitted by infected animal saliva from dogs, bats or wolves. There is a long and variable incubation period, commonly 1–2 months, but with a wide latitude

extending sometimes up to a year. The onset is then sudden, with a pyrexial illness, excitement, hydrophobia and violent muscular spasms involving the oesophagus and respiratory muscles. Crises are characterised by intense fury or profound terror, and in the intervals between the mind is clear. An ascending paralysis may occur. Death occurs during paroxysms, or in coma if the patient survives sufficiently long. Rabies must be distinguished from tetanus and from hysteria when a supposedly rabid dog has bitten a patient. In hysteria true pharyngeal spasm does not occur, and the mental disturbance is amenable to sedatives and suggestion.

Nipah virus

Nipah virus is a paramyxovirus that was first identified in Malayasia in 1998–1999. It is transmitted from pigs and was initially limited to farm workers (Goh *et al.* 2000). In comparison with other encephalitides, MRI may reveal multiple white matter lesions, which have been proposed to represent vasculitic lesions causing infarction (Lim *et al.* 2003). Ng *et al.* (2004) have reported the long-term neuropsychiatric sequelae of infection; eight of nine of their cohort presented with psychiatric symptoms, with depressive disorder both immediately after recovery and up to 1 year later being the most prominent. Cognitive deficits were also identified in attention, verbal and visual memory (Ng *et al.* 2004).

Non-geographically restricted sporadic encephalitides

Herpes simplex virus

The disease is severe, with mortality in untreated cases as high as 70% (Whitley *et al.* 1998) and long-term neurological impairments prominent in survivors. HSV shows certain special features including marked psychological disturbance in the acute phase and as a major sequel. Unlike the arboviruses, there are no seasonal or gender associations. The incidence has a bimodal spread, with one-third of cases occurring in the youngest age group up to 20 years and 50% of cases in those over 50 years (Tyler 2004). In a PCR investigation, HSV was responsible for 37% of all cases of encephalitis in subjects aged 60–65 years. The second bimodal peak may represent reactivation of latent virus in the elderly (Koskiniemi *et al.* 1996).

HSV encephalitis was controversial for many years because HSV infection is very widely distributed, with antibodies detectable in 80–90% of adults. It was also known that the virus could occasionally be cultured from random samples of CSF. However, the evidence that it truly caused encephalitis came from the finding of Cowdry type A inclusion bodies in the brains of affected persons, identical with those seen in cutaneous and visceral forms of the disease. Smith *et al.* (1941) were finally able to show a convincing association with acute encephalitis by isolating the virus

from the brain of a case which showed this specific pathological feature.

It is now recognised that HSV is responsible not only for cases of ordinary acute encephalitis but also for many of the cases of ‘acute inclusion body’, ‘acute necrotising’ and ‘haemorrhagic’ encephalitis that had formerly been regarded as distinct entities (Drachman & Adams 1962).

Pathology

Changes characteristic of other forms of encephalitis are seen: perivascular infiltration of lymphocytes and histiocytes in the cortex and adjacent white matter, proliferation of microglia and the formation of glial nodules. The cerebral cortex is mainly affected in adults, with less involvement of subcortical structures. A distinctive feature is the severity of the process. In areas of maximal involvement there is necrosis with softening, haemorrhage and loss of all nervous and glial elements. Such lesions tend to be asymmetrical between the hemispheres, and involve the medial temporal and orbital regions especially. In biopsy material obtained early in the disease it may be possible to demonstrate herpes viral antigen by immunofluorescence or immunoperoxidase techniques, thus confirming the diagnosis (Booss & Esiri 1986).

Clinical features

Only a small proportion of patients give a history of recurrent herpes labialis (Leider *et al.* 1965; Gostling 1967). Typically, there is rapid onset with a severe illness in the acute stage. There are no characteristic features that can distinguish HSV from other causes of encephalitis (Davis 2000). Pyrexia may be up to 39.5°C (103°F) and seizures may present in all age groups. In one study of symptom clusters in encephalitis and their PCR-identified virus correlations, HSV was more commonly associated with focal encephalitis (weakness, sensory abnormalities, aphasia, visual field defects and cranial nerve palsies) than diffuse disease (neurobehavioural change and alteration of consciousness) (Domingues *et al.* 1997).

Nonetheless, a high index of suspicion should remain even in atypical cases. Sometimes the clinical picture can at first be misleading and this is the position in perhaps as many as 20% of cases (Fodor *et al.* 1998). In five of six cases reported by Drachman and Adams (1962), psychological symptoms were the most striking initial feature. At first these patients appeared only mildly unwell and it was aberrations of behaviour that called attention to the seriousness of the illness. One patient packed a case a week in advance of a short journey, one dressed at night to go to an imagined funeral, one failed to recognise his wife and another slept until four o'clock in the afternoon then suddenly rushed from the house without explanation.

Once the illness is declared, a delirious phase is often prominent before the patient sinks into coma. Hallucinations

can resemble those of delirium tremens in being vivid and colourful, and in provoking a marked emotional reaction. On recovery from coma, behavioural disturbance may again be marked, with a phase of restless hyperactivity.

The prominence of psychiatric disturbance no doubt owes much to the characteristic accent of pathology on the temporal lobes and orbitofrontal structures (Greenwood *et al.* 1983). This may bring added focal symptoms such as anosmia, olfactory and gustatory hallucinations, or marked memory disturbance out of proportion to the impairment of intellect. Sometimes an area of focal necrosis becomes swollen to such a degree that the illness presents with features indicative of an acute intracranial mass, usually in the temporal lobe.

Much more rarely cases present with aseptic meningitis and run a benign course (Leider *et al.* 1965; Olson *et al.* 1967; Tyler 2004). Very occasionally there may be recurrent episodes of organic psychosis, as in the interesting patient reported by Shearer and Finch (1964): a 9-year-old boy had 17 episodes in a 3-year period, lasting a little over a week at a time, and consisting of fever, headache, drowsiness, disorientation and grossly irrational behaviour. Each episode was accompanied by EEG abnormalities and an outbreak of herpes labialis.

Investigations

Examination of the CSF should be carried out only if this is judged safe after performing CT (Solomon *et al.* 2007). Other infectious conditions can be excluded, and it may be possible to retrospectively demonstrate intrathecal synthesis of antibody to the virus, although this is not useful acutely as it takes weeks to develop (Boivin 2004).

Polymerase chain reaction is particularly useful for the detection of viral DNA in the CSF (Kleinschmidt-DeMasters *et al.* 2001), has high sensitivity (98%) and specificity (99%) (Puchhammer-Stockl *et al.* 1993) and allows the differentiation of recurrent viral infection and postinfectious immune-mediated disease (Boivin 2004). EEG shows non-specific slowing early on, and later periodic lateralising epileptiform discharges with a temporal focus (Steiner *et al.* 2005). EEG may need to be repeated, as these findings may only be temporary (Lai & Gragasin 1988).

Computed tomography can aid materially in excluding an abscess or tumour (Kaufman *et al.* 1979). The scan may be normal in the early stages, but later reveals characteristic low-density areas in one or both temporal lobes, or evidence of mass effects along with contrast enhancement (Zimmerman *et al.* 1980). MRI is more sensitive in revealing early changes at a time when therapy is most likely to be useful (Chaudhuri & Kennedy 2002). Cingulate gyrus and contralateral temporal involvement is extremely suggestive of HSV encephalitis.

Before the development of PCR techniques, brain biopsy was considered the gold standard for confirming the diagnosis. Type A inclusion bodies may be detected and the virus

demonstrated in the tissue obtained. However, the procedure is not without risk and a negative result does not exclude the condition. Rising titres of antibodies in the blood may give supportive evidence, but can be useful only in retrospect. Stereotactic-guided needle aspiration is now only rarely performed.

Tyler (2004) has discussed the discrepancies between different clinical presentations when confirmatory investigations by PCR or biopsy are considered. This appraisal identifies the variable presentations of encephalitis and the danger of assuming that what may have been considered atypical features, are not actually quiescent HSV encephalitis. PCR is considerably more sensitive, and cases with subtle changes in consciousness are much more readily identified by PCR than biopsy. Comparatively, personality change is slightly less common in PCR-identified cases.

Differential diagnosis

The disease is not infrequently puzzling. In addition to cases that present as possible tumours or abscesses, other conditions can be simulated. When pyrexia is low and neurological signs markedly asymmetrical, the picture may suggest subdural haematoma or head injury. Acute and fulminating examples may resemble meningitis. The prominence of mental confusion with vivid hallucinations may lead to a diagnosis of delirium tremens, or an acute onset with drowsiness, confabulation and fits may suggest Wernicke's encephalopathy. The residual end-state can closely resemble Korsakoff's psychosis or raise the possibility of neurosyphilis.

Treatment and outcome

Treatment is often a matter of urgency. Seizures should be controlled. Corticosteroids and mannitol may be required to reduce cerebral oedema, although their use requires further investigation (Openshaw & Cantin 2005). The nucleoside analogue acyclovir should be started as soon as possible in immunocompetent patients where there is strong suspicion based on the clinical history, neuroimaging and initial CSF findings (Solomon *et al.* 2007). Acyclovir resistance has been reported in immunocompromised patients and here foscarnet can be an effective alternative (Whitley *et al.* 1998). Decompression of the brain is a useful adjunct in appropriate cases.

Factors affecting treatment outcome include age, level of consciousness at presentation, viral load and duration of encephalitis (Tyler 2004). Kaplan and Bain (1999) identify time to treatment as the best indicator of outcome, although cognitive outcomes may be best predicted by the period of transient encephalitic amnesia, which is an equivalent concept to post-traumatic amnesia in head injury (Hokkanen & Launes 1997).

Before the advent of acyclovir, approximately 70% of patients died and half of the survivors were left with sequelae that could be severe (Illis & Merry 1972). With acyclovir

the prognosis has improved considerably, with fatal outcomes dropping to 20% (Sköldenberg *et al.* 1984; Whitley *et al.* 1986). However, when the temporal lobes have been damaged severely the consequences can still be grave. Mental retardation can ensue in children, or dementia in adults. Seizures, dysphasia, personality change and severe amnesic states have also been described (Oxbury & MacCallum 1973). Hierons *et al.* (1978) reported pictures ranging from relatively pure amnesic syndromes to severe dementia, often accompanied by bizarre behaviour reminiscent of Klüver–Bucy syndrome. The patients reported by Rose and Symonds (1960), in whom encephalitis was followed by a Korsakoff-like syndrome, were probably examples of HSV encephalitis.

The risk of cognitive impairment has been shown to be two to four times higher than that of patients with other causes of viral encephalitis (Warrington & Shallice 1984; Hokkanen *et al.* 1996; Pewter *et al.* 2007). Cognitive outcomes include dense anterograde amnesia in 25–75% (Hokkanen & Launes 2000) with variable retrograde memory impairment, which may also present in isolation (Baur *et al.* 2000; Harlam *et al.* 2001; Tsukiura *et al.* 2003). Dysexecutive features may also present in some 40% (Kapur *et al.* 1994), with impaired performance on frontal testing (Del Grosso Destrieri *et al.* 2002; Shoqeirat *et al.* 1990; Hokkanen & Launes 1997). Category-specific anomia or more widespread semantic impairments are a frequently reported sequel (Barbarotto *et al.* 1996; Moss & Tyler 2000; Schweizer *et al.* 2001). Even among patients who apparently make excellent recoveries after treatment with acyclovir, neuropsychological testing may reveal evidence of cognitive deficits. Gordon *et al.* (1990) followed four such patients for several years, and all showed deficits on language and memory tests. Some showed additional impairments in calculation, visuoconstructive ability and facial recognition, and none were able to function at their prior level of achievement. Such results underline the importance of careful follow-up evaluation and counselling in patients who have had the disease.

Long-term psychiatric outcomes are also prominent. McGrath *et al.* (1997) identified a prevalence of personality and behavioural disturbance of 45%, taken from the medical records of survivors of HSV encephalitis at between 6 months and 11 years. Schizophreniform psychoses and emotional lability are rare but have also been reported (Vallini & Burns 1987; Gaber & Eshiett 2003), sometimes a considerable time after treatment and discharge.

Type B HSV encephalitis

The monkey form of HSV produces an almost invariably fatal disease in humans, and is a hazard to workers in animal laboratories. It is transmitted by the bite of an infected monkey. A vesicle is produced at the site of entry, and along with encephalitis of severe degree there is often an ascending

paraplegia. Widespread necrotic lesions are found in other organs as well as the brain.

Epstein–Barr virus

The neurological complications of infectious mononucleosis rarely include an encephalitic picture. When this does occur it may be due to direct viral invasion of the nervous system, but sometimes it appears to represent an allergic encephalomyelitis similar to that following the acute exanthemata. A benign lymphocytic meningitis (see Meningitis in this chapter) can also occur. The incidence of neurological sequelae in infectious mononucleosis is 0.4–7.3% (Silverstein *et al.* 1972).

Headache and meningism often accompany glandular fever. Diffuse EEG abnormalities have been reported in up to 30% of cases. However, frank neurological complications are rare. Gautier-Smith (1965) and Boughton (1970) have described patients with acute confusion progressing to stupor or coma, usually setting in abruptly within 5–9 days of the illness. Other cases present with seizures or focal cerebral disturbances such as hemiplegia. Pommer *et al.* (1983) reported the case of a 43-year-old patient who presented with transient global amnesia and seizures after EBV infection. Siversten and Christensen (1996) identified the onset of a severe dementia in one case from their cohort. Syndromes of brainstem, cerebellar or cord dysfunction may also be seen. The CSF shows a moderate rise in cells and protein. Complete recovery appears to be the rule.

Of considerable interest are patients who develop acute psychiatric disturbances in clear consciousness during the course of glandular fever. Raymond and Williams (1948) described a patient who became acutely psychotic within a few days of onset, settling over 3 weeks as the illness improved. Klaber and Lacey (1968) reported 5 of 76 cases presenting with severe psychiatric disorder during the course of an epidemic, only subsequently being diagnosed as suffering from glandular fever. Two showed pictures of acute schizophrenia and three acute depression. Here it seems likely that the patients were responding to the non-specific stress of the physical illness rather than to direct nervous system involvement.

More recently, Behr *et al.* (2006) reported the psychiatric presentation of an immunocompromised post-transplant patient.

A 58-year-old man presented with emotional lability, depressed mood, anhedonia and loss of appetite 2 months after a bone marrow transplant for myelodysplastic syndrome. Three months later he presented with cognitive dysfunction. MRI demonstrated a frontal lesion consistent with a vascular malformation and, later in the presentation, non-enhancing periventricular hyperintensities. His cogni-

tive state deteriorated with disorientation, poor attention and concentration, as well as impaired short-term memory. Mental state examination revealed a dysphoric mood, blunted affect and psychomotor retardation and no alteration of consciousness. On physical examination, he was afebrile and there were no focal neurological signs or meningism. EBV genome copies in peripheral blood leucocytes revealed reactivation of EBV. CSF examination identified a pleocytosis, raised protein and oligoclonal banding restricted to the CSF. Intrathecal syntheses of IgM antibodies and intrathecal production of IgG anti-EBV antibodies indicated a reactivated cerebral EBV infection. PCR for EBV DNA in CSF was positive.

EBV and fatigue

A depressive aftermath has also been widely reported following EBV, very occasional patients showing depression of psychotic intensity (White & Lewis 1987). Careful prospective studies by White, P.D. *et al.* (1995a,b) have shown that a persistent fatigue syndrome may develop in the 6 months following glandular fever, and that to a large extent it could be differentiated from depression. Whereas social adversity correlated significantly with the development of depression, this had little association with the development of a fatigue syndrome or delayed physical recovery (Bruce-Jones *et al.* 1994). An investigation by Hamblin *et al.* (1983) could be relevant in pointing to immunological dysfunction. However, a prospective study of 71 patients with infectious mononucleosis from primary care revealed that predictors of fatigue over 1 year had no clear immune or neuroendocrine predictors but that psychosocial factors and illness perceptions were predictive at various stages (Candy *et al.* 2004). Early mobilisation may have a protective effect.

In these and other cases of chronic fatigue that appears to follow a viral infection, general rehabilitative principles apply with attention paid to treating manifest or masked psychiatric disorder. Wessely *et al.* (1989, 1991) and Sharpe *et al.* (1996) give detailed descriptions of a cognitive-behavioural approach which aims, *inter alia*, to break the vicious cycle of exercise avoidance leading to diminished exercise tolerance and the production of further symptoms. Encouragement of the patient to engage in graded activity by planned stages requires careful assessment of the capacities in each individual and full explanation of the aims of treatment.

Enterovirus encephalitis

The enteroviruses are more likely to produce the picture of aseptic meningitis than encephalitis (see Meningitis, later). The poliomyelitis virus is distinguished by its effects on the

spinal cord and the accompanying encephalitis is usually very slight in degree, but the related coxsackieviruses and echoviruses can occasionally produce definite encephalitic manifestations.

Outbreaks are commonest in summer and autumn. The illnesses caused by coxsackieviruses and echoviruses usually run a benign course, accompanied by other systemic symptoms characteristic of the virus concerned: maculopapular rashes, muscular pains or pleurodynia. The changes in the CSF resemble those of poliomyelitis, with a moderate elevation in protein, normal sugar and 50–100 cells/mm³ (polymorphs early and mononuclear cells later). The virus may be isolated from throat swabs or stool specimens, but is of more significance if found in the CSF. A rise in serum antibodies may be demonstrated during the course of the disease by neutralisation or complement fixation tests, although many asymptomatic infections evoke the same response. Serological testing is also made difficult by the large number of antigenically distinct viruses in this group.

Children affected before 1 year of age may occasionally be left with neurological impairment and seizures (Sells *et al.* 1975). Otherwise serious sequelae are uncommon with coxsackievirus and echovirus infections. Muscular weakness may persist for some time during convalescence, but true paralysis is rare. Poser *et al.* (1969) have reported the occasional development of postencephalitic parkinsonism after such infections, but this is usually a transient and mild disability unlike that following encephalitis lethargica (see Encephalitis lethargica, later).

Other sporadic viral encephalitides

In a great number of cases of sporadic encephalitis the cause is never identified, and the yield even with extensive virological studies remains rather low. The following known varieties are all relatively infrequent.

Varicella-zoster virus

Varicella-zoster virus is the cause of either chickenpox or shingles, depending on the immunocompetence of the patient. Some degree of meningeal reaction is common in herpes zoster, with elevation of the protein and an excess of mononuclear cells in the CSF. Features of meningitis are observed very occasionally and encephalitis occurs in up to 5% of those hospitalised with shingles and in less than 0.05% of those hospitalised with chickenpox (Mazur & Dolin 1978; Guess *et al.* 1986). Hall (1963) has reported a clear example of encephalitis following ophthalmic zoster and resulting in a chronic amnesic syndrome.

Hokkanen and Launes (2007) have reviewed the neuropsychiatric sequelae of herpes zoster encephalitis. They note that the acute-stage cognitive profile has not been adequately studied but that deterioration in verbal and visual reasoning, perseveration, poor recent and remote memory, attention, concentration, planning and impulse control have

all been reported. Hallucinations have been reported in a number of case studies in the acute stage, but are likely a non-specific feature of delirium (Jemsek *et al.* 1983). Psychosis, irritability and mood change have been reported both acutely and after recovery (Hokkanen *et al.* 1997; Hokkanen & Launes 2007). Cognitive characteristics after treatment have equally received only limited attention, with the suggestion that outcomes are more favourable than in HSV encephalitis, with perhaps a subcortical picture being evident in some cases (Hokkanen *et al.* 1997).

Mumps encephalitis

It appears that the mumps virus affects the nervous system more commonly than was previously supposed, even in the absence of parotitis or other typical evidence of the disease. This is probably the only common childhood infectious disease in which the virus itself can invade the CNS. Prior to the development of routine vaccination, an aseptic meningitis (see Meningitis, later) was most commonly seen, although an encephalitic illness is also reported. When it occurs there is usually some degree of coincident meningitis and sometimes myelitis. Mumps encephalitis in adults is nowadays extremely rare.

Symptoms appear some 2–10 days after the onset of parotitis, but can precede it or occur without any overt evidence of mumps elsewhere in the body. Meningeal symptoms are usually prominent, with headache, vomiting, fever, neck stiffness and irritability. Drowsiness and delirium occur, sometimes with cranial nerve palsies, ataxia or pareses in the limbs. Fits are uncommon. In the acute myelitic form there is profound paresis and sensory changes in the limbs. The varied psychiatric and neurological pictures that may be seen are reviewed by Keddie (1965).

The CSF shows a moderate pleocytosis, usually of mononuclear cells, from the outset. Serological tests are useful if a rise in titre of complement fixation or haemagglutination-inhibition antibodies can be demonstrated during convalescence. Permanent sequelae are common enough to suggest that the prognosis should be guarded (Lees 1970; Johnstone *et al.* 1972).

Other para-infectious encephalitides

The forms of encephalitis that occasionally follow the acute exanthemata account for a large proportion of the cases seen in childhood. The chief causes are measles, rubella, pertussis and scarlet fever, although similar developments may be seen after viral pneumonias and infectious mononucleosis. The incidence of encephalitis in measles has been estimated as 0.1%, varying by age, with only 10% of cases occurring in adults (Gibbons *et al.* 1956) and mortality being 15–25% in the 1950s to 1960s. Encephalitis associated with rubella infection has a reported incidence of 0.2 per 1000 rubella cases, with mortality around 20% (Miller *et al.* 1956).

In Kennard and Swash's (1981) series, the predominant antecedent of many of these illnesses was an upper respiratory tract infection of influenzal type. All share a common pathology and possibly a common pathogenesis. Closely similar illnesses may follow vaccination against smallpox or injections of serum, or sometimes they arise for no apparent reason. The brain may be involved alone or there may be more widespread effect throughout the neuraxis with brainstem or cord involvement. In such cases the term 'acute disseminated encephalomyelitis' is usually employed.

The pathological changes differ from those of the virus infections already described in certain definite respects, though some degree of overlap can be seen. The brain and cord show congestion, often with petechial haemorrhages. However, the most striking changes are seen in the white matter, with discrete areas of acute perivenous demyelination, mononuclear perivascular infiltration and neuroglial proliferation. There is no evidence of a direct attack on the nerve cells themselves, and the cortical neurones are characteristically spared completely unless there has been a complicating factor such as hypoxia (Booss & Esiri 1986). In acute haemorrhagic leucoencephalitis, the changes are particularly severely developed, along with brain congestion and swelling and foci of perivascular necrosis. There is little to suggest direct invasion of the CNS by the viruses concerned. Allergic or autoimmune mechanisms are generally held to be the cause as the picture closely resembles that of experimental allergic encephalomyelitis.

The clinical picture consists of headache, drowsiness, photophobia and irritability, setting in some 3–14 days after the onset of the specific illness but with wide latitude of timing. There is commonly an interval of normal health between the acute viral illness and the encephalopathic development. Convulsions are common and meningism is often prominent. Cranial nerve palsies may appear, or myoclonic and choreiform movements may be seen. Loss of abdominal reflexes and extensor plantar responses are usual findings. The brainstem may be principally involved, with vertigo, vomiting, nystagmus and dysarthria; alternatively, in myelitic forms there may be paraparesis with retention of urine. Peripheral nerve involvement is common. The CSF may be normal, but is often under increased pressure with a mild lymphocytic pleocytosis and moderate elevation of protein. CT or MRI may show multiple white matter abnormalities similar to those of multiple sclerosis, or more extensive symmetrical changes in the cerebral and cerebellar white matter and basal ganglia (Kesselring *et al.* 1990). Serial MRI can be useful in contributing to the distinction from multiple sclerosis in uncertain cases. Textbooks of neurology should be consulted for further details of the pictures seen with different infections.

If the patient does not succumb during the first week or two a remarkably complete recovery may be seen. The mortality is much higher in infants than in older children or

adults. In some survivors there may be severe neurological sequelae, with hemiparesis, paraparesis, epilepsy and impairment of intellect. In children, behaviour disorders similar to those that follow encephalitis lethargica may occur. In adult survivors, varied neuropsychiatric sequelae have been reported after measles and rubella encephalitis, including schizophreniform psychosis (Stoler *et al.* 1987) and widespread impairments of memory, executive function, language and perception in some cases, similar to those seen after cases of HSV encephalitis (Pewter *et al.* 2007).

Subacute sclerosing panencephalitis

Subacute sclerosing panencephalitis (SSPE) is a rare disease in the developed world, with just 10 cases reported annually in the USA (Garg 2002). It remains rare in developing countries, but higher incidences are reported, for example 21 cases per million in India. The majority of cases have a history of measles infection. The initial features of the illness include more subtle cognitive impairment deteriorating into behavioural disturbance and clear-cut dementia. It is in this context that problems of differential diagnosis usually arise. Sometimes, however, the possibility of other psychiatric illness is raised in the early stages. Myoclonic jerks involving the head, trunk and limbs may be seen in later stages. Visual changes are reported in 10–50%, including cortical blindness, chorioretinitis and optic atrophy. In the most advanced stages the patient becomes quadriparetic with gradual decline into coma.

Cases were first described by Dawson in 1933 (subacute inclusion body encephalitis), van Bogaert in 1945 (subacute sclerosing leucoencephalitis) and Brain *et al.* in 1943 and 1948. These now appear to be essentially variants of the same disease process (Adams 1976).

Pathology

Adams (1976) described the typical pathological picture. The brain may be normal macroscopically, or firm and shrunken with areas of focal necrosis. Microscopy shows evidence of subacute inflammation, usually in both the grey and the white matter. There is perivascular infiltration with lymphocytes and plasma cells, and proliferation of astrocytes and microglia. Slight meningeal infiltration may also occur. The white matter lesions are of particular interest in that they are closely similar to those seen in para-infectious encephalomyelitis and HAD (Poser 1990). In the grey matter neuronal degeneration is apparent, often with characteristic intranuclear inclusions, and in the white matter areas of demyelination are seen with fibrous gliosis. Considerable variation is encountered from case to case.

The typical 'type A' intranuclear inclusions are strongly acidophilic homogeneous bodies with a sharp outline, separated from the nuclear membrane by a clear halo. They are the feature that originally suggested a viral aetiology, and are similar to those which occur in HSV encephalitis (see Non-geographically restricted sporadic encephalitides, later). In

severely degenerated cells the inclusions may fill the nucleus so that the surrounding cytoplasm is reduced to a vestige. Sometimes they are found in the cytoplasm itself, or in glial cells as well as neurones; such changes may be focal in distribution (see Kennedy 1968).

Evidence has accumulated to suggest that the measles paramyxovirus is responsible. Almost all patients have a history of measles, usually at an early age, or of measles immunisation. Very high antibody titres to the virus are found in the serum and CSF, and specific immunofluorescence with measles antibody has been demonstrated in brain biopsy material (Connolly *et al.* 1967; Legg 1967). Electron microscopy has shown particles indistinguishable from paramyxovirus budding from cytoplasmic inclusions, and measles virus has been isolated from brain cell tissue cultures derived from patients with the disease (Horta-Barbosa *et al.* 1969). Finally, the disease has been transmitted to animals by intracerebral inoculation of brain tissue from patients with the disorder (Lehrich *et al.* 1970).

It remains unclear why such an illness should develop in a minute proportion of those who have suffered a primary measles infection. The virus probably gains access to the brain at the time of initial infection and develops into a less invasive and more persistent form that evades immune destruction (Anderson 1993). The original infection may have been with an unusual strain of virus. At some stage the latent infection then triggers an immune-mediated response that results in the widespread pathological changes in the brain. Possibilities of reactivation by subsequent infection, even by a different organism, have not been discounted.

Clinical features

The great majority of cases occur in children or adolescents, although occasional examples have been reported in middle age (Brierley *et al.* 1960; Himmelhoch *et al.* 1970) and are probably to be regarded as variants of the disease.

Classic examples present with insidious deterioration of intellect, such that the child begins to fail at school, becomes forgetful and inattentive, slowed and slovenly. Other early symptoms are nocturnal delirium with hallucinations, marked lethargy and difficult uncontrollable behaviour. The prodromal manifestations may occasionally occur alone for a period of several months, but neurological abnormalities generally develop early. Characteristically the patient develops marked involuntary movements, including myoclonic jerks of the face, fingers and limbs, athetosis or rapid torsion spasms of the trunk that lead to sudden stumbles and falls. Myoclonia may be regularly periodic, occurring at fixed intervals of 5–10 seconds for hours or days at a time. The limbs develop bilateral extrapyramidal rigidity or progressive spasticity. Epileptic fits are common, and aphasia, apraxia or akinetic mutism may appear. A low-grade pyrexia may accompany the prodromal or later stages of the disorder, but this is not invariable.

Atypical presentations sometimes raise the possibility of non-organic psychiatric illness in the early stages. For example, Koehler and Jakumeit (1976) reported a woman of 20 who presented with an apparently hysterical blindness and gave Ganser responses of a classic nature. She showed a profound lack of initiative and spent much of the time asleep. Within a week of admission, however, the true disease was declared. In the 21-year-old patient described by Salib (1988), who presented with dysmorphophobic features, the diagnosis was delayed for several months and schizophrenia was suspected initially.

Electroencephalography often shows highly characteristic features, though many variants occur. Typically there are high-voltage slow-wave complexes, synchronous in all leads, and occurring at fixed intervals of 5–10 seconds along with the myoclonic jerks. They may also appear in the absence of motor abnormalities and can sometimes be focal in the frontal or occipital regions. The CSF may show a slight increase in cells, but the total protein is often normal. A feature of diagnostic importance is that the majority of cases show a raised IgG in the CSF and a paretic curve on Lange's colloidal gold test. The complement fixation titres for measles are high in serum and CSF. CT or MRI may show white matter abnormalities and later atrophy of the cerebrum, cerebellum and brainstem (Jayakumar *et al.* 1988).

The first descriptions stressed that the disease had a hopeless prognosis, with rapidly progressive dementia over 6 weeks to 6 months and death after a period of coma and Decerebrate rigidity. However, cases have since been reported with temporary arrest for months or even years in the middle stage of the disorder, and very few have been described with partial recovery. Of Kennedy's (1968) five cases in children, two achieved remission and one returned to school after regaining much coherent speech and a diminution of myoclonic jerks. Resnick *et al.* (1968) followed a patient for 5 years who showed considerable sustained improvement despite the continued elevation of measles antibody in serum and CSF. Cobb and Morgan-Hughes (1968) mention other scattered examples in the literature and suggest that the following patient may have had the disease in a mild form.

A 21-year-old chemistry student was admitted with a 5-month history of falling attacks, momentary blank spells and recent difficulty with concentration. Neurological examination was normal apart from brisk reflexes, EEG showed persistent slow waves in the left occipitotemporal region, and CSF showed a paretic Lange curve. He was readmitted 8 months later with impairment of memory and difficulty with reading, writing and calculation, which had come on over the preceding 2 months. He showed a severe

global dementia, with loss of recent memory, disorientation in time, agraphia, acalculia and profound constructional apraxia. The Wechsler Adult Intelligence Scale (WAIS) showed a verbal IQ of 79 and a performance IQ of less than 35. Affect was flattened and inappropriate. Neurological examination was still negative, but EEG showed bilateral recurrent monophasic and biphasic slow-wave complexes.

He was treated with prednisone in addition to anticonvulsants and slowly improved. By the following year he was working, although he had been dismissed from several jobs on account of general slowness and difficulty with reading and writing. Seven years later he was working as a gardener and had recently married. He was still mildly dysgraphic, with reading difficulties and profound constructional apraxia, but he was orientated in time and place and able to do simple calculations. Psychological testing showed a verbal IQ of 82 and a performance IQ of 40.

Risk *et al.* (1978) estimated that improvement could be expected in about 5% of cases, even after severe illnesses. However, relapse may subsequently occur after remissions lasting for several years. Their experience with 118 patients showed substantial long-term improvement in six. Two of these were still improving 4–5 years later, two were stable 4–6 years later, and two relapsed after 8 and 11 years respectively. Remittent cases tended to have shown milder variants of the disease and to have been somewhat older than usual at onset.

Progressive rubella panencephalitis

A variant of SSPE has been described in which rubella rather than measles virus appears to be responsible (Townsend *et al.* 1975, 1976; Weil *et al.* 1975). This sets in, usually during the second decade, in children who have been affected by rubella *in utero*. Mental and motor deterioration develop as with SSPE, and the pathological changes in the brain are similar. The serum and CSF show elevated titres of antibodies to the rubella virus and normal titres to measles. The rubella virus has been isolated from the brain in such cases.

Other varieties of subacute encephalitis

Himmelhoch *et al.* (1970) reported an interesting group of eight cases, mostly in adults, some apparently representing variants of SSPE. Symptoms characteristic of functional psychiatric disorder were prominent in all, and seven had originally been diagnosed as suffering from depression, schizophrenia or hysteria. In some the onset was acute, with sudden withdrawal and seclusiveness following a period of coryza, malaise and headache. Retardation was prominent and a psychogenic reaction was usually diagnosed at this stage. The patients then quickly developed disorientation

and visual hallucinations and showed intellectual deterioration. In others the development was more protracted, with irritability, depression, phobias and ruminations over a period of several months. They then became mute and retarded and showed progressive intellectual impairment.

The bizarreness of behaviour had strongly biased the initial diagnoses, and neurological signs had often been ignored even when they were noted. Evidence of mild confusion, disorientation or visual hallucinations had sometimes been disregarded, changes of sleep and appetite had been ascribed to depression, and fugue-like states to catatonia or hysteria.

Characteristically there were rapid fluctuations, with impaired awareness and disorientation one day followed by complete lucidity the next. Periods of aggressiveness and sexual provocativeness were often followed by profuse apology, and patients seemed bewildered by their behaviour. Bizarre behaviour became increasingly frequent as time went on. It was markedly unresponsive to pharmacotherapy. Hallucinations were mainly visual but occurred in other modalities, and clear-cut paranoid delusions were common. At times an isolated episode was hard to distinguish from schizophrenia.

There were no consistently helpful laboratory findings, but all patients showed abnormal EEG changes at some point in the disease. Some died within several weeks or months, some ran a protracted course with remissions, but three recovered to premorbid levels of intellectual functioning (Himmelhoch *et al.* 1970).

A housewife of 38 became deluded after a period of fever, coryza and headache. She was committed to hospital with a diagnosis of paranoid schizophrenia. She alternated between a delusional state, when she was boisterous, abusive and combative, and periods of complete lucidity. Neurological examination revealed nothing abnormal, and her behaviour was unresponsive to phenothiazines or electroconvulsive therapy. Her later course was stormy, with grand mal seizures and periods of coma. EEG showed episodic, synchronous, high-voltage slow waves alternating with periods of relative electrical suppression. Biopsy of the right temporal lobe showed the features of encephalitis but no inclusion bodies were found.

Over the next 3 months the patient made a partial recovery, but 6 months later she still had severe impairment of memory, with disorientation for time and place and occasional nocturnal seizures. Five years later her memory deficit had cleared markedly, but the seizures continued and she had developed progressive paraplegia. The measles antibody titre remained elevated in the serum.

A 35-year-old woman graduate with a stable previous history became abruptly combative, confused and 'animalistic'. EEG was diffusely slowed, and the CSF showed a mild pleocytosis. She became unkempt, cachectic and totally uncommunicative, and showed aggressive and sexually provocative behaviour. She was incontinent of urine and faeces and required tube feeding. Even so she had intermittent periods of complete lucidity.

One month later she began to improve, with lessening of memory deficit and improvement of intellectual functions. At the same time, however, her behaviour became increasingly difficult to control. She refused to attend group meetings, with biting, kicking or pulling up her dress when she was urged to attend. With her family she behaved rather better and ultimately she was discharged. Two further admissions were required in the next few months on account of disturbed behaviour, but thereafter she unexpectedly began to improve. At first she had to carry a notebook to help with her memory, but after 18 months this became unnecessary. After 2 years she had recovered completely and continued to function normally.

Brierley *et al.* (1960) reported another group of three patients, all with onset in the fifties and all of whom were diagnostic problems during life. One had been regarded as having dementia, but in the others a low-grade pyrexia early in the illness had raised the possibility of a viral encephalitis. One presented as a severe depressive illness coloured by bizarre behaviour and later developed minor epileptic attacks, another began with depression following a respiratory infection, and the third began with pains in the shoulders and arms then progressed to tiredness and depression over the course of several weeks. At post-mortem all showed severe encephalitic changes concentrated to a notable degree on the medial temporal lobe structures. Inclusion bodies were not present.

Differential diagnosis

Subacute encephalitis clearly gives rise to diagnostic confusion during life. It is a rare condition, so that the clinician is unlikely to see more than the very occasional case. Difficulties with diagnosis are especially likely to arise in the prodromal period. In children the picture may suggest behaviour disorder or autism, and in adults other psychiatric disorder may be simulated as described above. Careful attention must be directed towards minor neurological abnormalities, sudden involuntary jerks, evidence of nocturnal delirium or intermittent low-grade pyrexia.

Alzheimer's disease is probably the commonest misdiagnosis in the later stages in adults. Multiple sclerosis may be suggested by the combination of early neurological

disability with a paretic Lange curve and negative reactions for syphilis in the CSF. HSV encephalitis can show identical inclusion bodies in biopsy material, but the course is acute, and progressive dementia and myoclonic jerking are not seen.

Classic examples of SSPE usually declare themselves eventually when involuntary movements and typical EEG features appear. Diagnostic brain biopsy may be required as a last resort.

Adenovirus encephalitis

Adenovirus infections are discussed by Booss and Esiri (1986). The several varieties are associated with acute respiratory infections, conjunctivitis and pharyngitis. Adenovirus type 7 may lead to encephalitis in children with respiratory disease, sometimes in the form of small outbreaks. Adult adenovirus encephalitis is rare and often comorbid with other conditions. The outcome is often complete recovery, although residual ataxia (Zagardo *et al.* 1998), language and visual construction impairment (Hokkanen *et al.* 1996), irritability, mood change and amnesia (West *et al.* 1985; Hokkanen *et al.* 1996) have been reported.

Influenza encephalitis

The neurological manifestations of influenza virus have been reviewed by Studahl (2003). It appears that the influenza virus itself may be responsible for occasional cases of encephalitis, perhaps with a greater incidence in children (Morishima *et al.* 2002). Small groups of cases have been reported during influenza outbreaks in many parts of the world, including the large epidemic of 'Asian' influenza (influenza type A) that affected the British Isles in 1957–1958.

A variety of pictures is seen, some setting in at the height of the upper respiratory tract infection, others beginning towards the end of the attack, and others following some days later after a brief afebrile episode. The usual picture is of headache, vomiting, delirium and coma, with transient reflex abnormalities or weakness of the limbs. The CSF may be normal or show a slight pleocytosis. EEG is often diffusely abnormal. The illness usually resolves after several days and excellent recovery is said to be the rule. Sulkava *et al.* (1981) reported four cases of encephalitis after type A influenza, with transient changes in memory, fatigue and mental 'sluggishness' that resolved within a month of recovery.

In other varieties the patient shows no more than a period of mental confusion and headache, accompanied by EEG abnormalities and succeeded by complete amnesia for the episode (Bental 1958). Cases have been reported from Barbados with an unusual hallucinatory syndrome in which bizarre smells were experienced (Lloyd-Still 1958). Other forms include spinal and radicular syndromes, transverse myelopathy and ascending motor and sensory disturbances

of the Guillain–Barré type (Flewett & Hoult 1958; Wells 1971). Severe, non-specific, transient, neurological sequelae have been reported after the influenza type B epidemic in Chicago in 1971 (Hochberg *et al.* 1975) and in Dallas in 1977 (Baine *et al.* 1980). Neuroimaging has identified widespread involvement of the cerebral cortices, subcortical white matter or thalamus, lesions in the brainstem, basal ganglia and cerebellar white matter after influenza encephalitis (Studahl 2003).

The nature of the causal relationship between these illnesses and the influenza virus remains uncertain. They are rare, even during extensive epidemics, and it is hard to exclude the possibility of coincident infection with another sporadic virus. Dunbar *et al.* (1958) estimated that their cases represented only 1 in 10 000 of the persons affected by the influenza epidemic in the area. Other possibilities are the activation of some associated neurotropic virus or the occasional development by mutation of a neurotropic strain of influenza virus. Kapila *et al.* (1958) were able to isolate influenza type A virus from the brain substance of one fatal case, but such reports are few. Examples that occur at the height of an attack may sometimes be merely attributable to the cerebral anoxia and metabolic derangements consequent on pneumonia. However, the evidence increasingly favours the view that the great majority represent an autoimmune or hypersensitivity response on the part of the brain, similar to that which occurs after other infective illnesses (see below), and precipitated by the presence of virus in the body but not necessarily within the brain (Anon. 1971). The pathology in fatal cases often supports this view by showing perivascular demyelination similar to that of postinfectious encephalitis generally.

The broader question arises of the relationship between influenza and other psychiatric disturbances that follow it. Depression appears to be common and may sometimes be unusually refractory to treatment; this has been ascribed to invasion of the brain by the influenza virus but there is no direct evidence to support the view (Anon. 1971). Psychological reactions may also be seen, and are usually ascribed to the non-specific stress of the illness and the physically weakening effects of its aftermath.

Steinberg *et al.* (1972) reopened this question by presenting a case that suggested a more direct pathophysiological relationship between the infection and a manic psychosis that followed.

The illness, in a woman of 21, began with a typical attack of influenza. After a brief remission she again became febrile, with headache, sore throat and an unproductive cough. She complained of paraesthesiae in the limbs and experienced a transient episode of blindness lasting for less than a minute. Over the next 2 weeks a typical manic illness developed, with evidence of confusion and disorientation during the

first few days. The affective disturbance gradually subsided with treatment over the next few months.

Antibody titres to influenza A were abnormally high at the onset, and showed an unusually slow decline in comparison with other influenza patients while the manic illness was resolving. Despite normal findings in CSF and EEG, the authors postulated that a mild attack of influenza encephalitis had probably occurred, producing minimal brain damage which acted as an intervening factor and contributed to the subsequent affective disorder.

The evidence is clearly tenuous, but combined virological and psychiatric studies on a larger number of patients might illuminate the relationship further as Steinberg *et al.* suggest. Neuropsychological impact has been reported by Hokkanen *et al.* (1996) in a small case series of influenza type B encephalitis. The outcomes are largely favourable but further evaluation of cognitive effects is needed.

Encephalitis lethargica

An earlier generation of neurologists and psychiatrists were much concerned with this disease on account of the devastating epidemics of 1918–1920 and the chronic sequelae that occurred. From the 1930s onwards it largely disappeared, at least in its original form. Sporadic cases continue to appear in the literature with a degree of regularity (Shill & Stacy 2000; Kiley & Esiri 2001; Dale *et al.* 2004, 2007; Gonul *et al.* 2007; Raghav *et al.* 2007) but there have been no further epidemics. Strangely, no causative organism was isolated despite extensive research, and laboratory proof has never been available to uphold the diagnosis in disputed cases. This remains the case in sporadic reports of the disorder, where it has been impossible to identify viral particles in the CNS. Von Economo's assertion that influenza virus was not implicated has been borne out by examination of the archived encephalitis lethargica brain material, which has failed to reveal 1918 influenza RNA (Taubenberger *et al.* 1997; McCall *et al.* 2001). Recent interest has been directed to an autoimmune cause in light of the presence of CSF oligoclonal bands in a number of cases (Dale *et al.* 2004) and a treatment response to steroids (Blunt *et al.* 1997).

Historically, the thousands of cases available for observation displayed a wealth of psychopathological phenomena that could be clearly ascribed to pathological changes in the brain. This had an important influence on psychiatric thinking at a time when psychodynamic explanations for mental pathology were gaining significant ground. Certainly it focused attention on the relation between mental symptoms and brain structure in a way few affections of the nervous system had done before. The sequelae of the disease demon-

strated that an organic basis could sometimes exist for 'functional' disturbances, including tics, psychosis, far-reaching disturbances of personality and, particularly, compulsions and other profound disturbances of will. Hendrick (1928) reviews the attempts that were made by psychiatrists of every school to capitalise on the lessons to be learned from encephalitis lethargica for understanding the neuroses and psychoses, and von Economo (1929) wrote

... just as we find it hard today to follow up the trend of thought of our scientific predecessors for whom bacteriology and the lore of brain localisation did not exist, future generations will hardly be able to appreciate our pre-encephalitic neurological and psychiatric conceptions, particularly with regard to so-called functional disturbances.

There is, of course, a danger that these important lessons will be forgotten with the passage of time. The clinical features of the disease are therefore described in some detail.

Encephalitis lethargica was first reported by von Economo in 1917, after a small local epidemic had led to numerous patients being seen in the Vienna Psychiatric Clinic with strange symptoms that did not fit into any known diagnostic category. The shared features were slight influenza-like prodromata followed by a variety of nervous manifestations, marked lethargy, disturbance of sleep and disturbance of ocular movement. At post-mortem the picture of microscopic foci of inflammation, particularly in the grey matter of the midbrain and basal ganglia, was sufficiently constant to suggest a common cause despite the variety of phenomena that occurred. Complete recognition followed in the great pandemic that started in London in 1918 and spread throughout Europe during the next 2 years, approximately coincident with the influenza pandemic of that time. The polymorphic forms of the disease continued to be a striking feature, fresh epidemics often running close to type and differing from those nearby both in the acute phases and in the incidence of sequelae.

There was a seasonal pattern, with most epidemics beginning in early winter. The peak incidence was in early adult life, from age 15 to 45 years, though no age group was spared. At one time a toxic agent was suspected, but the general pattern combined to suggest an airborne infective agent, gaining access via the nasopharynx and transferred by carriers or those in the presymptomatic stages of infection. The agent was shown to be filterable and the disease was transmissible to monkeys by injection of brain tissue from infected patients, but the cause itself continued to elude attempts to isolate it. It was a matter of controversy whether the coincident influenza epidemics had predisposed the host to react abnormally to some relatively innocuous organism, and some evidence suggested that the herpes virus might itself be responsible. These questions were not decisively settled, but the great majority of contemporary

epidemiological evidence suggested that an independent virus was responsible.

In retrospect it appeared that this was not entirely a new disease, and similar widespread epidemics could be traced in history. von Economo was at least somewhat aware of this in that his mother recalled an epidemic of a similar stuporose disorder in Italy, the *nona*, in 1890–1891 and contemporary writing reported a similar illness described as the *Schlafkrankheit* in Tübingen in 1712. In England a second peak of encephalitis lethargica occurred in 1924, but thereafter there was a striking fall-off of new cases throughout the 1930s, although sporadic cases continued to be seen and small local epidemics appeared from time to time.

The following description is largely taken from von Economo's (1929) classic account.

Acute clinical picture

A prodromal stage lasting several days consisted of malaise, mild pharyngitis, headache, lassitude and low pyrexia, all symptoms being slight and resembling the prodromata of influenza. A great variety of nervous symptoms then appeared, depending on the localisation of the virus within the CNS.

The 'basic' form, and that most usual in sporadic cases, was the *somnolent–ophthalmoplegic* variety. Somnolence developed after the prodromal phase, with slight signs of meningeal irritation. Initially there was merely a tendency to drowsiness from which the patient could easily be roused, sometimes with evidence of confusion or mild delirium. If recovery did not occur at this stage, the disorder progressed further to more or less permanent sleep for weeks or sometimes months, often deepening to coma. On recovery, disturbances of sleep function might persist for many months during convalescence. Pareses of the cranial nerves set in early, especially of the third and sixth, with ptosis, paralysis of ocular movements and less commonly pupillary abnormalities or nystagmus. Such signs were usually persistent, but sometimes fugitive and fleeting. Facial palsy or bulbar palsy occasionally developed. In the limbs isolated pareses and reflex abnormalities were seen, with spasticity, hypotonia or ataxia.

In other cases the picture was dominated after the prodromal stage by signs of motor unrest. This was the *hyperkinetic form*, with myoclonic twitches, severe jerking chorea, wild jactitations and anxious excited behaviour. Sometimes compulsive tic-like movements, torticollis and torsion spasm appeared. Oculomotor signs and epileptic fits were common. Delirium could be marked, with constant unrest by day and night, sometimes closely resembling delirium tremens with anxiety amounting to terror in response to vivid hallucinations. Typically the acute disturbance lasted only a few days, but insomnia or reversal of sleep rhythm then usually persisted for weeks or months after recovery.

The *parkinsonian form* was characterised by rigidity and

akinesia from the outset. Movements were remarkably slowed and sparse, the patient lying still for hours at a time or responding with profound psychomotor retardation. Speech, like motor movements, was greatly delayed, yet the patient could be shown to be mentally intact despite the appearance of dementia. The limbs showed increased tone and often a coarse tremor. The gait was festinant, and salivation occurred as in paralysis agitans. Catatonic phenomena could be seen, including classic *flexibilitas cerea*. Along with these features somnolence, sleep inversion and oculomotor signs might be in evidence. Many progressed thereafter to the chronic parkinsonian phase of the disease.

The *psychotic forms* were rare, but presented with acute psychiatric disturbance as the initial feature. Here mistakes in diagnosis frequently occurred until neurological signs declared themselves. The usual picture was of an acute organic reaction, but stupor, depression, hypomania and catatonia were also reported. Sometimes impulsive and bizarre behaviour was the sole manifestation for several days, accompanied by bewildered and fearful affect. Alternatively, mental conflicts were brought to the fore, adding a psychogenic colouring to the presenting symptoms. Several examples were reported by Sands (1928).

A woman of 28 developed a sore throat lasting a week. A few days later she became excited, rambling and impulsive and was diagnosed as suffering from manic-depressive psychosis. No neurological abnormalities were found. She became extremely fearful, asking whether she was about to die or if something terrible was going to happen to her family. She spoke irrelevantly and was very tense. The pupils were later found to be irregular with sluggish reactions, and the tendon reflexes were diminished. In the following week she developed choreiform and athetoid movements and a left facial weakness. She died a few days later after a period of disorientation, high pyrexia and noisy disturbed behaviour.

A woman of 32 suddenly became restless and noisy, sang and screamed, and claimed to be the daughter of Christ and impregnated by him. She lay in bed in a strained attitude, and was markedly deluded and uncooperative. The pupils were widely dilated and reacted sluggishly to light, and the tendon reflexes were diminished. She continued in a state of excitement for 3 days then became drowsy, with diplopia and irregularity of the pupils. Three weeks later she recovered completely.

A woman of 30 developed headache for 2 days, then became excitable, restless and uncooperative. She was admitted to hospital with a diagnosis of manic-depressive psychosis. She proved to be deluded and occasionally hallucinated, and claimed at times to be a physician or a great singer. Her temperature was found to be 38.9°C (102°F), and the CSF was under increased pressure with 6 cells/mm³. Many weeks later she developed ocular palsies and other neurological signs typical of encephalitis lethargica.

It was disputed whether some cases might run their course as a psychotic illness alone without somatic symptoms at any stage. This could neither be proved nor disproved owing to the lack of specific tests for the disease. However, in 1924 the Board of Control in the UK reported that many patients had been admitted to mental hospitals with diagnoses of non-specific confusional, delusional and hallucinatory states, yet in later years proved to show the classic sequelae of encephalitis lethargica (Anon. 1966). The psychiatric literature abounded with case reports, and arguments centred on whether the cases had been missed because the neurological signs had been mild and fleeting, or whether the disease could present as a 'cerebral' form without localised manifestations.

Other forms presented with acute bulbar palsy, or monosymptomatically with intense chorea, persistent hiccough or neuritis. Abortive types were common in most epidemics, with symptoms capable of arousing suspicion during the epidemic but easily overlooked at other times. During the acute phase there was usually rapid debility and loss of weight. Fever might accompany the prodromal phase or persist throughout, while other cases ran their whole course without pyrexia. A moderate leucocytosis was often present but was not invariable. Examination of the CSF was not in any way decisive, although most cases showed some abnormalities. Many abortive cases developed only the prodrome, while others recovered early after definite symptoms and signs had appeared. Some ran a fulminating course with death after a few days or weeks. Usually, however, the acute disturbances lasted for several weeks, with some months more before ocular palsies, lethargy and sleep disturbances resolved.

A protracted convalescence was not uncommon, with repeated relapses and fresh exacerbations. Convalescence also brought prolonged asthenic states, incapacitating depressive illness and a variety of sleep disturbances: insomnia, sleep inversion and narcoleptic phenomena.

On recovery, focal neurological abnormalities might persist. Paralysis of external ocular movements or of isolated eye muscles was frequently permanent, also pupillary abnormalities, difficulty with accommodation and inability

to converge the eyes. Hemiparesis, aphasia or other focal cerebral symptoms might remain, likewise chorea, tics, torticollis or epilepsy. Hypothalamic damage was seen in adiposity, menstrual disturbance, impotence or precocious puberty. However, the outstanding sequelae were parkinsonism and changes of personality as considered below.

Altogether in clinically well-marked acute cases, some 40% ended fatally, 40% were left with residual deficits and 20% recovered completely. Approximately half of those with residual deficits were permanently disabled from working, mostly on account of progressive parkinsonian symptoms (von Economo 1929).

Chronic sequelae

The most seriously disabling sequelae consisted of parkinsonian developments, change of personality and mental defect. Severe psychiatric illnesses were also seen. The incidence of each varied in different epidemics, but a definite relationship emerged with regard to the age at which the acute infection had occurred. Adults tended to develop parkinsonism, children personality disturbances, and infants were left with mental defect. Generalised dementia did not appear to occur when the mature brain had been affected.

Parkinsonism sometimes developed gradually out of the acute stage, or could set in unexpectedly after full recovery. In the interval the patient may have shown persistent symptoms such as headache, irritability and sleep disturbance but this was by no means invariable. Indeed as time went by it became apparent that sequelae could develop after many months or years of completely normal health. In contrast, personality change and mental defect were usually evident immediately after the acute infection. The severity of sequelae was unrelated to the severity of the original attack.

Postencephalitic parkinsonism

This was the most common sequel and could develop even when parkinsonian symptoms had been absent during the acute phase. Its development was usually insidious, with weakness and slowing of movements or the gradual development of a stiff and unnatural posture. The ensuing picture closely resembled other forms of parkinsonism, with mask-like face, stooping posture, festinant gait and excessive salivation. Tremor was less common than in paralysis agitans; the typical pill-rolling tremor was rarely seen, but coarser tremor and violent shaking of the limbs occasionally occurred.

Paucity of movement was sometimes a striking sign even in the absence of paresis or marked rigidity. It appeared that in large degree this represented a *primary disturbance of willed movement*, such that the patient was unable to supply the volitional impulse despite a wish to perform. There might be much difficulty in passing from rest to activity, the patient remaining for minutes on end in a state of trance-like immobility. Or a movement once started might freeze halfway, as

when raising a spoon to the mouth. Later typical rigidity developed, with extrapyramidal increase of tone that was obvious on examination. Characteristically, the akinesia and the rigidity could vary markedly, improving at some stage during the day, or allowing some activities while preventing others that required exactly the same musculature. Speech became slurred, jerky and monotonous, and writing was often strikingly small and cramped (micrographia).

Other distinctive features were *repetitive motor phenomena* in the form of tics, blepharospasm, torticollis, spells of sighing and yawning, or complex respiratory spasms. Complicated motor stereotypies developed in advanced cases, for example stamping of the feet accompanied by writhing movements of the head and neck. Speech might show marked repetitive phenomena: of a phrase (echolalia), word (pallilalia) or syllable (logoclonia).

A *compulsive element* was often very prominent indeed, and emerged in speech and thought as well as in motor behaviour. A repeated phrase or question might accompany the motor movements, or the latter might be 'subjectivated' in a characteristic fashion; the patient would state 'I have got to move my hand that way' rather than 'I have a twitch in my hand' as would be the case with ordinary tics. Compulsive thoughts and urges also appeared independently of the motor phenomena, with the patient ruminating endlessly on restricted themes or being driven to complex rituals. Compulsive urges sometimes led to trouble with the law, for example with repeated episodes of indecent exposure. Claude *et al.* (1927) reported patients with compulsions to tear their clothes, pull out teeth, tie themselves with bonds and to strangle cats; they stressed the abrupt appearance of the obsessions, their fixity over time and the patient's clear awareness of the absurdity of the acts. It is of considerable theoretical interest that motor and psychological features of compulsion should so regularly have occurred together and in intimate association. Schilder (1938) considered that the compulsive phenomena could often be directly traced to motor sources. The encephalitic process liberated motor impulses, with a tendency towards impulsive actions of a sadistic nature, and when checked these led in turn to the compulsions.

Oculogyric crises were another characteristic feature, again often intimately associated with compulsive phenomena. For a few minutes, or rarely hours, the eyes would deviate upwards or to the side, perhaps with contortions of the head, neck and extremities. Flushing and other autonomic disturbances were common accompaniments. At the onset the patient might be beset by some obsessive thought or enact some complex compulsive ritual. The crisis was sometimes accompanied by a fugue-like mental state, with inability to speak and lack of response to commands, or by marked affective disturbance: surges of depression, anxiety or fear, ideas of reference or feelings of persecution. Schwab *et al.* (1951) mention a patient whose episodes of paranoia were localised

to one side of her body during oculogyric crises: she felt that everything and everybody on her left were hostile and unfriendly, whereas the environment on her right was normal. When the attack was over her thinking returned to normal. Suggestibility was sometimes found to be an important factor, oculogyric attacks being provoked by talking about them or terminating in response to a sharp command. Attacks could also be precipitated by annoyance, shock or grief, and could be contagious in a ward of patients similarly affected. Thus again we see the complex admixture of motor and psychological phenomena that characterised the disease.

The typical mental state in postencephalitic parkinsonism was of marked slowing (bradyphrenia) and lack of the normal fluidity of thought, though otherwise with good preservation of mental clarity. Depression was common, in the early stages at least, and suicide was frequent. Torpor, irritability and disinclination for activity usually accompanied the compulsive elements of the disease (psychasthenia). Later, apathy became the striking emotional feature, with marked difficulty in arousing an affective reaction and little evidence of subjective distress. The parkinsonism itself usually advanced steadily, sometimes with intermittent progressions, but sometimes came to a halt with fixed residual defect. The combination of physical and mental disabilities inevitably meant that a large number of victims were permanently incapacitated for work, and such patients came to form a substantial proportion of the chronic mental hospital population. Oliver Sacks (1973) has provided a striking account of the remarkable motor and behavioural abnormalities encountered in a group of very long-term institutionalised survivors in the USA, and of the effects of attempted treatment with levodopa.

Postencephalitic personality change

Children and young adolescents were mostly the victims of this serious development, but adults were not completely immune. It was estimated that approximately one-third of patients below the age of 16 developed some form of mental change after encephalitis lethargica. Frequently it was accompanied by other sequelae such as parkinsonism, sleep disturbance, obesity or other evidence of hypothalamic damage.

The common change was towards overactivity and impulsive antisocial behaviour, as though the child now had lessened control over his instinctual drives. He became excited and restless, with inability to settle at school or remain occupied at any task for long. He was talkative, importunate and disinhibited, often indulging in stealing or sexual misbehaviour. Emotional lability was marked, with cheerful affectionate behaviour one moment and outbursts of anger the next. Moral and social senses were undermined, so that the child became destructive, abusive and hard to control. There was usually no primary intellectual deficit, although

as time went by education suffered severely or became impossible. Frequently the child appeared to be aware of the change in himself, to apologise repeatedly, yet immediately afterwards be compelled to err again. The subsequent course was often unfavourable, with worsening over the years leading eventually to institutionalisation. Fairweather's (1947) account of postencephalitic patients admitted to Rampton State Institution for patients with violent and dangerous propensities gives a vivid illustration of the pictures that could ensue, with repeated serious aggression, sexual perversions and self-mutilation. At puberty improvement occurred in perhaps one-third of cases. In later years some 50% developed parkinsonian changes, with ultimate benefit where the behaviour disorder was concerned (Slater & Roth 1969).

Postencephalitic psychoses

A variety of psychotic illnesses supervened in other patients on recovery from the acute stages. Depression and hypomania were relatively common, also paranoid-hallucinatory states and a variety of illnesses resembling schizophrenia. Severe hypochondriasis of 'psychotic' severity was often reported.

Hall (1929) described 18 patients from among 113 cases of encephalitis lethargica, mostly with manic-depressive psychoses or schizophrenia. They differed from the generality of psychoses in that delusions were more transient and variable, and even relatively mild depression was accompanied by profound retardation and immobility. Fairweather (1947) noted that 25% of men and 12% of women admitted to Rampton after encephalitis lethargica were deluded, mainly in a paranoid fashion.

Davison and Bagley (1969) review the evidence concerning schizophrenia. Paranoid-hallucinatory psychoses were estimated to occur in 15–30% of postencephalitics, and psychoses indistinguishable from paraphrenia or dementia praecox in 10% of those admitted to mental hospitals. All reported patients were selected for psychiatric disorder so the true frequency is unknown, but clearly such developments were not uncommon. Davison and Bagley's analysis of 40 cases from the literature revealed only one with a schizoid premorbid personality and two with family histories of schizophrenia, discounting the view that there was usually a predisposition towards the disorder.

Present-day encephalitis lethargica

It would be a matter of some importance if sporadic cases of the disease were common and indeed some authors have suggested that the disease continues at a low endemic rate (Dale *et al.* 2007). This raises the possibility that there may be a substantial chance that the diagnosis could be overlooked, especially with mild affections, yet the sequelae might still dictate considerable psychiatric disability. The problem is difficult to resolve: the laboratory findings were variable

when the disease was epidemic, and specific confirmatory tests were not achieved.

Recently, however, the suggestion that the present-day encephalitis lethargica phenotype may be immune-mediated has gathered momentum. Dale *et al.* (2004) reported 20 cases, including two adults, with a classical neuropsychiatric presentation. Over half of these cases had suffered pharyngitis or tonsillitis prior to developing the illness, with an associated positive anti-streptolysin-O titre in two-thirds. None had evidence of viral encephalitis. The CSF showed elevated protein and oligoclonal IgG bands, previously also noted by Howard and Lees (1987), Blunt *et al.* (1997) and Kiley and Esiri (2001). Neuroimaging in 40% revealed inflammatory changes in basal ganglia and midbrain tegmentum. These changes were shown to resolve on recovery. Perhaps most interestingly, anti-basal ganglia antibodies were identified on Western blot in 95% of cases, with similar immunohistochemistry to Sydenham's chorea. Giovannoni and Martino (2004) have suggested that encephalitis lethargica is likely part of the spectrum of immune-mediated neuropsychiatric sequelae of streptococcal infections that also includes PANDAS (paediatric autoimmune neuropsychiatric disorders associated with *Streptococcus*) (Swedo *et al.* 1998).

Most recently, Dale *et al.* (2007) identified two hyperkinetic cases with impulsive and compulsive behaviours, rabbit-like orofacial dyskinesia and sensitivity to neuroleptics as well as dopaminergic drugs. They suggest dopamine depletion followed by dopamine-receptor hypersensitivity as a neurochemical model for encephalitis lethargica.

Dewar and Wilson (2005), in reporting a further case, review the cognitive outcomes of contemporary reports of encephalitis lethargica. They identify the limited formal evaluation of neuropsychological outcomes in the majority of case reports and go on to identify impaired executive function, concept formation, complex mental flexibility, verbal abstraction and non-verbal recall in their patient. They advocate the importance of cognitive rehabilitation.

Blunt *et al.* (1997) identified the benefit of steroids and levodopa in two cases.

One patient had a psychosis and a mute-akinetic syndrome associated with myoclonus. The second patient presented with a psychosis and fever, developing severe dyskinesias involving the mouth, trunk and limbs, together with respiratory irregularities and presumed hypothalamic disturbance and disturbance of consciousness. In both cases, initial CSF examination revealed an elevated white cell count (predominantly lymphocytes), elevated protein in case 2, and oligoclonal bands in both cases. CT of the brain was normal but in both cases EEG revealed diffuse

slow-wave activity. ^{18}F -dopa PET in case 2 was normal. In case 1, levodopa improved the akinesia, while the myoclonus responded to clonazepam. In case 2, the severe dyskinesias failed to respond to a number of drugs, and she ultimately required paralysis to relieve her almost continuous movements. Both patients responded rapidly and dramatically to intravenous methylprednisolone.

Rail *et al.* (1981) reviewed eight further examples occurring during the preceding two decades, some presenting with prominent psychiatric features. Pathological examination of the brain in two patients showed extensive loss of neurones from the substantia nigra and locus coeruleus, along with widespread neurofibrillary changes elsewhere in the brainstem, dentate nuclei and corpus striatum. They stressed that the diagnosis still rested essentially on the clinical features, and suggested that the following criteria be applied: an encephalitic illness, parkinsonism developing acutely or after a delay of months or years, alteration in the sleep cycle, oculogyric crises that are not drug induced, ocular or pupillary changes, respiratory disturbances, involuntary movements, corticospinal tract signs and mental abnormalities. While these represent the specific features of encephalitis lethargica, it is clear that not all will be present in every case.

Johnson and Lucey (1987) have reported two suspected examples in young men, both presenting with severe catatonic stupor in the setting of depressive psychosis. One had a low-grade pyrexia and the other showed blepharospasm and complex compulsive rituals.

The debate concerning latter-day examples was extended by Hunter and Jones (1966), who argued that sporadic cases might be appearing in mild or attenuated form and with clinical pictures increasingly dominated by psychiatric manifestations. Consequently, the neurological signs on which the diagnosis depends could readily be overshadowed. They reported six possible cases seen during a 3-month period in a psychiatric hospital. All had presented with psychiatric syndromes, and all had initially been seen at general hospitals where diagnoses of hypomania, depression and anxiety neurosis had been applied.

Two were admitted in a state of excitement and confusion, two after overdoses of sleeping pills, one in a catatonic state and one at his own request on account of feeling ill and 'nervous'. Most had a history of progressive personality change over the course of several months, with irritability, emotionality, perplexed-paranoid developments and impaired memory and concentration. They complained of malaise, headache, lethargy, hypersomnia, insomnia, giddiness, blurred and double vision, and altered taste and

smell. All had worsened in the week or two before admission, with increasing agitation and depression, paranoid and bizarre bodily delusions, and nocturnal excitement and hallucinosis.

On examination all showed some degree of mental confusion, three had mild pyrexia and all had some ocular abnormality. A variety of other neurological signs were present, often fluctuating from day to day. The authors suggested that the range of symptoms and presumed cerebral localisation was strongly reminiscent of encephalitis lethargica.

It is extremely difficult to evaluate these examples, but perhaps encephalitic antecedents should more often be considered in the differential diagnosis of psychiatric patients. Hunter *et al.* (1969) pursued the question further by examining the CSF in 256 patients admitted to a psychiatric unit. More than one-quarter showed minor biochemical abnormalities and some who underwent serial measures showed a return to normality when the clinical condition improved.

Leigh (1946) and Espir and Spalding (1956) reported other cases in the context of acute influenza.

A police cadet of 16 developed headache and later that afternoon was found unconscious in bed. An hour later he was confused and talked nonsense. In the evening he lost consciousness again and was admitted to the Radcliffe Infirmary, Oxford. On examination he responded to painful stimulation but did not speak. There was a pyrexia of 37.8°C (100°F) and some nasal discharge. Myoclonic twitching was observed around the mouth and in the limbs. The pupils were unresponsive to light and the right eye was deviated laterally. All limbs were flaccid with normal tendon reflexes but with bilateral extensor plantar responses. The CSF was under pressure (240 mmHg) but showed normal constituents. The white blood count was normal. EEG showed a generalised disturbance but no focal abnormalities. The fever subsided next day but the level of consciousness fluctuated over the next 3 weeks. There were almost continuous involuntary movements of chewing, swallowing, yawning and writhing of the limbs. He was occasionally incontinent of urine. The pupils became unequally dilated, conjugate movements of the eyes were defective in vertical directions, and slight left facial weakness appeared.

Thereafter he slowly recovered and was discharged 2 months after the onset. He was still almost completely mute and apt to have crying spells, but within the next few weeks he was speaking normally and returned to work a month or two later. During the next 18 months he complained of undue sleepiness by day and was treated with dexamfeta-

mine sulphate. In other respects he seemed to have recovered completely. Subsequently, however, he committed a series of crimes, mainly of a violent and unpremeditated nature and with little attempt at concealment. Previously he had been of exemplary character. The legal proceedings which followed brought him under medical supervision some 4 years after the initial illness. He then described episodes lasting 15–20 minutes during which his eyes involuntarily turned upwards and to the right in a manner strongly suggestive of oculogyric crises. There was occasional titubation of the head, his facial expression was stiff and there was slight cogwheel rigidity of the upper limbs.

Espir and Spalding support their diagnosis of encephalitis lethargica by pointing out that such a picture is rarely produced by the many known types of present-day viral encephalitis. Ophthalmoplegia is rare with other varieties, and parkinsonism a distinctly uncommon complication. The prolonged sleep disturbance during convalescence was also typical.

It is also worth considering whether encephalitic processes may have contributed to the prevalence of 'catatonia' in earlier psychiatric practice. Mahendra (1981) reviews the decline of 'catatonic schizophrenia' over the past 40 years, and suggests that many examples in the earlier literature may have owed much to a viral, and possibly an encephalitic, origin. Present-day catatonia, when it occurs, may be seen in association with an impressive range of physical conditions, ranging from brain lesions and infections to toxic and metabolic disorders (Gelenberg 1976). In the absence of clearly organic determinants it appears now to be associated with affective disorder very much more commonly than with schizophrenia (Abrams & Taylor 1976).

Meningitis

Meningeal infection is less liable to lead to diagnostic problems than encephalitis. In most varieties pyrexia and neck stiffness are soon in evidence, headache is marked and lumbar puncture rapidly confirms the diagnosis. Tuberculous meningitis is the important exception, sometimes presenting with insidious and ill-defined mental changes as described below. Enduring sequelae are also less common after meningitis than encephalitis provided full and effective treatment has been instituted early. Three varieties are discussed: bacterial meningitis, aseptic meningitis and tuberculous meningitis.

Bacterial meningitis

The principal organisms responsible are *Neisseria meningitidis*, *Streptococcus pneumoniae*, *Staphylococcus aureus*,

Haemophilus influenzae and *E. coli*. In a nationwide study of community-acquired meningitis in the Netherlands, van de Beek *et al.* (2004) identified that among adults *N. meningitidis* accounted for 37% of cases and *Strep. pneumoniae* 51%. The introduction of a conjugated vaccine for *Haemophilus* has had a significant impact on the number of such cases in the developed world (Schuchat *et al.* 1997).

Headache is usually the presenting feature, with pyrexia and rapidly increasing evidence of general ill health. Vomiting, photophobia and irritability are common from an early stage. Fits are frequent in children but rare in adults. Mental disturbance takes the form of an acute organic reaction, with drowsiness extending to coma and sometimes hallucinations, excitement and other features of delirium.

Neck stiffness and a positive Kernig's sign are important confirmatory features. Pupillary abnormalities and oculomotor palsies are common, slight incoordination or tremor may appear in the limbs, and the tendon reflexes are sluggish. The plantar reflexes are sometimes upgoing. Van de Beek *et al.* (2004) found that 95% of their cohort presented with at least two of the four cardinal symptoms: headache, fever, neck stiffness and altered mental status.

The CSF is under increased pressure and is often cloudy or frankly purulent. Polymorphonuclear cells may number thousands per cubic millimetre, and the protein is raised. The causative organisms may be cultured or demonstrated on films.

Bacterial meningitis can result in damage to both cortical and subcortical areas and neurological outcomes are obviously dependent on the degree and location of injury. In a study in England and Wales, Bedford *et al.* (2001) described outcomes in 1584 children who had meningitis at age 5 and who had been treated for the disease and survived. In this group 1.8% had died within 5 years and there was a 10-fold increased risk of having moderate to severe disability: 7.5% had learning disability, 8.1% motor disability, 7.3% seizures, 25.8% hearing impairment and 12% behavioural disturbance. Those with pneumococcal infection had higher rates of significant disability than those infected with *Haemophilus* or *N. meningitidis*. Impairments have been shown to persist into adolescence, 7 years after early meningitis. Grimwood *et al.* (2000) reported that of their cohort of 109 children, 9% continued to have major neurological, hearing or learning disability and 30% had less severe impairments compared with 11% of controls.

In adults, Hoogman *et al.* (2007) conducted a large, prospective, multicentre investigation of cognitive outcome in adult survivors of meningitis. Thirty-two per cent had cognitive impairment, with those who had survived pneumococcal infection performing poorly on memory tasks and psychomotor speed compared with those who had been treated for meningococcal meningitis. Cognitive slowness was stable over time after acute infection, and male sex and cranial nerve involvement were predictors of poor

cognitive outcomes. The prevalence of cognitive disturbance was similar for both pneumococcal and meningococcal infection.

In another study, over 70% of adult survivors had neurological and mental symptoms at 3 years after acute infection, with poorer outcomes in those infected by *Strep. pneumoniae* (Merkelbach *et al.* 2000). There were again reductions in psychomotor speed as well as concentration, visuoconstructive capacity and visual memory and generally lower psychometric performance scores compared with verbal subscales. The pattern was consistent with that observed in subcortical cognitive disorders. Interestingly, Beck Depression Inventory scores in this group were significantly higher than in the controls and did not correlate with neuropsychological test results. Similarly, increased risk of cognitive slowness or cognitive disorder has been corroborated in other studies and many report that *Strep. pneumoniae* may be particularly implicated (van de Beek *et al.* 2002; Weisfelt *et al.* 2006a,b), although the most recent and statistically powerful sample does not support such a difference (Hoogman *et al.* 2007).

In adults, mild but prolonged depression is common during convalescence, no doubt partly as a reaction to the stress of the illness. A period of fatigue and inefficiency may precede full recovery, and loss of libido may last for several months. Pai (1945) investigated 51 adults after meningococcal meningitis, all of whom were seen in a neuropsychiatric unit. Sulphonamides had been used in the treatment of some but not all cases. Sixteen patients showed intellectual deterioration or organic change of personality, and these were the ones who had had severe meningitis with marked delirium. In the other 35 patients psychogenic factors seemed to predominate. Disorders of gait and hysterical paresis had often set in after complete recovery and could be related to external stress. Depression was almost universal. Evidence of pre-morbid instability could often be discerned, but not in every case. Four patients had developed obsessional disorders for the first time. Other symptoms such as headache, blackouts and temporary loss of memory were occasionally hard to apportion to psychogenic or physiogenic causes.

Aseptic meningitis (acute benign lymphocytic meningitis)

Broadly speaking, aseptic meningitis can be defined as any type of meningitis where CSF bacterial cultures are negative. Viral meningitis is by far the most common aetiology, with the enteroviruses (including poliomyelitis, coxsackievirus and echovirus) being most frequently incriminated in some 80% of cases (Rotbart *et al.* 2004; Lee & Davies 2007). In their study of the causes of aseptic meningitis and encephalitis in an adult population, Kupila *et al.* (2006) reported confirmed diagnoses in only 50% of cases, highlighting often inconclusive investigations. Enterovirus infection accounted for 46% of cases, HSV-2 31%, and VZV 8%. Other viral causes include

acute lymphocytic choriomeningitis virus, EBV and other herpes viruses. HIV infection must also be borne in mind (see Acquired immunodeficiency syndrome, earlier). Non-viral causes must also be considered, including the early stages of tuberculous meningitis, brain abscess, neurosyphilis, leptospirosis and particularly incomplete treatment of bacterial meningitis. There are a number of non-infectious causes to consider as well: iatrogenic (including post vaccination and medication-related cases), collagen vascular disorders, sarcoid and neoplastic disease (Kumar 2005).

Viral meningitis occurs across the lifespan but is particularly common in younger children. The incidence in those aged over 16 in the large 1966 birth cohort from Finland was 7.6 per 100 000 (Kupila *et al.* 2006). Cases occur in small epidemics and also arise sporadically. Epidemics are commoner in the summer and autumn when the circulation of enteroviruses among the population reaches a peak.

The onset is abrupt with symptoms similar to those of bacterial meningitis, but most illnesses are mild, running a course of 2–10 days then subsiding spontaneously. General malaise may persist for several weeks thereafter. Occasionally, the meningitic symptoms and the CSF abnormalities persist much longer and tuberculous meningitis may then be diagnosed in error.

The CSF is under increased pressure and contains 50–1000 cells/mm³, of which most are lymphocytes. The protein is elevated but the chloride and glucose content are usually normal. CSF cell count does not reliably differentiate bacterial and viral aseptic meningitis. Dubos *et al.* (2006) suggest that the combination of CSF protein and serum procalcitonin may be helpful discriminators between bacterial and aseptic causes in children up to 16 years old. Testing of the CSF with PCR is commonly undertaken for enteroviruses, herpesviruses and VZV. Positive identification of a viral cause has an impact on antibiotic prescribing and length of hospital stay (Ramers *et al.* 2000).

Enduring sequelae are distinctly rare, except for the paralysis that follows poliomyelitis and some infections with coxsackievirus type A7. On the other hand, minor temporary debilities are fairly common during convalescence. Muller *et al.* (1958) carried out a long-term follow-up of a large group of cases of aseptic meningitis and 'meningoencephalitis of unknown cause', and compared them with controls from the normal population. No major differences could be found with regard to mental symptoms, occupation, school performance or social adjustment. Of 238 patients, only four were definitely mentally disordered with impaired capacity for work, two had epilepsy, two had tonic pupils and two had endocrine disorder. There appears to be no increase in chronic fatigue following viral meningitis as opposed to other viral infections and it seems to be predicted by psychiatric morbidity and prolonged convalescence rather than by the severity of the viral illness itself (Hotopf *et al.* 1996).

Tuberculous meningitis

In 1998, the WHO reported that some 2000 million people across the world were infected with tuberculosis, although only 10% presented with clinical manifestations. Tuberculous meningitis, in contrast to its pulmonary and other extrapulmonary counterparts, had predominantly been a disease of the young. However, in HIV-positive subjects, the risk of infection with tuberculosis increases to one in three (Selwyn *et al.* 1989) and there is also a contingent increase in cases of tuberculous meningitis (Bishburg *et al.* 1986) that correlate with decreasing CD4 counts (DeCock 1997).

The macroscopic cerebral pathology is characteristic. A yellowish, gelatinous, inflammatory exudate forms mainly at the base of the brain in the anterior basal cisterns, brainstem and cerebellum and extending along the lateral sulci. The basal exudate is often organised and adherent, obstructing the flow of CSF and leading to hydrocephalus and also damage to efferent cranial nerves. Arteritis is prominent in large and small vessels and areas of infarction may occur. Miliary tubercles are visible on the leptomeninges and along the principal cerebral arteries. Microscopically, the inflammatory reaction can be seen to involve the floor of the third ventricle but is usually nowhere pronounced. The neurones show degenerative changes and old caseous foci can often be found in the substance of the brain.

This more than any other form of meningitis is liable to lead to diagnostic error. Thwaites and Hien (2005) have reviewed the diagnostic and treatment dilemmas at length. The onset is insidious, fever is low grade and often considerably delayed, and neck stiffness can be very slight. Meningism is not characteristically reported, with only 2% presenting these symptoms initially. Many of the clinical features are non-specific, making it difficult to arrive at the diagnosis on history and examination alone (Kent *et al.* 1993; Hosoglu *et al.* 1998). Recent exposure and extrameningeal tuberculosis are features that may increase suspicion (Karstaedt *et al.* 1998).

A prodromal phase of vague ill health is usual, lasting for 2–3 weeks or longer. Anorexia is marked (60–80%), but headache may be transient or even absent at this stage. Mental changes form an integral part of the picture, typically apathy, irritability and insidious change of personality. As long ago as 1868, Trousseau stressed that ‘sadness setting in unaccountably is a premonitory sign of great value in a child’. Williams and Smith (1954) found that the earliest mental changes in their cases were often so gradual that they were imperceptible except to those who knew the patient well beforehand. A change towards clouded awareness was usually the first definite sign, the patient lying quietly and without apprehension. In one case the presenting symptom was of subjective impairment of memory.

As the disease progresses, headache (50–80%) intensifies and low-grade pyrexia develops. Focal signs appear in the form of palsies of cranial nerves III (5–15%), VI (30–40%) and

VII (10–20%), coarse tremor of the limbs and reflex abnormalities. Hemiplegia (10–20%) or other gross neurological defects may occur, and seizures present in around 50% of children and 5% of adults. Papilloedema is a late development, but choroidal tubercles are seen in the retina in up to 20% of cases (Wiles 1993b). These are rounded or oval yellow patches, approximately half the size of the optic disc.

The CSF is under increased pressure, with a lymphocytosis of 100–1000 cells/mm³. The protein is increased in the majority of cases, the sugar is reduced in around 70% and the chloride also much reduced. Atypical CSF findings are not uncommon in those who have HIV and sometimes also in the elderly. The diagnosis is confirmed when tubercle bacilli can be identified or cultured from the fluid, but this is not achieved in every case: if there is strong diagnostic suspicion, analysis should be repeated. Large volumes of CSF may be required (10 mL is recommended). CSF culture of mycobacteria is the gold standard investigation but takes up to 8 weeks.

Computed tomography and MRI may show hydrocephalus, oedema, tuberculomata, focal infarcts and exudate in basal brain cisterns. The latter two are highlighted by gadolinium-enhanced T1-weighted images, making MRI preferable (Rovira *et al.* 1980; Bhargava *et al.* 1982; Bullock & Welchman 1982; Tartaglione *et al.* 1998). Nonetheless, it is unclear whether neuroimaging is effective in discriminating between tuberculous meningitis and other cerebral pathology. MRI is considered to be preferential to CT in identifying brainstem and cerebellar pathology.

The mental abnormalities increase, with drowsiness, confusion, disorientation and inability to sustain a rational conversation. Characteristically, the patient sleeps when alone but becomes disturbed when roused, in contrast to the perpetual ‘silent struggling delirium’ of purulent meningitis. Occasionally the patient is hallucinated and wildly delirious. The terror may resemble that of delirium tremens, or Wernicke’s encephalopathy may be simulated when the onset is abrupt and oculomotor palsies are present. Formerly, typhoid was often suggested by the combination of headache, fever and delirium.

Without treatment progressive hydrocephalus develops, coma (30–60%) supervenes and the patient dies in a state of decerebrate rigidity. The ‘confusional’ stage has been reported to evolve during treatment to an ‘amnesic’ stage which may last for many weeks. Williams and Smith (1954) have described this picture in detail. Throughout the amnesic phase the patient is usually euphoric and shows little concern about his memory difficulties (neurosyphilis is important in the differential diagnosis; see Syphilis of the CNS in this chapter). Some, however, are withdrawn, negativistic, paranoid or acutely depressed. During recovery, memory continues to lag behind improvement in other intellectual faculties. Retention of current events improves gradually, or occasionally returns with dramatic suddenness. The period of retro-

grade amnesia meanwhile steadily contracts towards the time of onset of the illness.

With cure of the infection, as judged by the return of the CSF to normal, there is usually a complete restitution of normal memory functions, although a persistent amnesic gap remains for the period of overt confusion and disorientation. Williams and Smith followed 19 cases for periods of up to 4 years; none showed measurable defects of intellect, personality or memorising ability, although four complained of subjective forgetfulness for minor day-to-day events. Three others complained of slight impairment of concentration or were said by their relatives to show a lessened sense of responsibility. However, all were amnesic for the early weeks or months of the illness, even those who had seemed alert and rational throughout. Six had a persistent retrograde amnesia, sometimes extending for periods of months or years prior to the illness, with haziness for details, some complete gaps and inability to organise past events into the correct temporal sequence.

A young man of 22 developed severe tuberculous meningitis. He had a long and difficult illness requiring some 9 months of treatment. Three years later he was doing well in clerical work and had recently been promoted. His memorising of current experience was normal. However, he still had a substantial retrograde amnesia for events some 6 months before the clinical onset of his illness, and had entirely lost some specific skills such as typing acquired during this period. The amnesia extended also to the first 4 months of the illness itself.

With present-day management a full physical and mental recovery can usually be secured when diagnosis has been prompt. Williams and Smith (1954) found that the majority of patients returned gradually to their former efficiency. Headache or neurotic developments were conspicuous by their absence. However, when neurological complications have been grave at the height of the illness there may be residual hemiparesis, paraparesis, epilepsy or intellectual impairment in association with hydrocephalus. Blindness or visual defects may result from optic atrophy, and deafness occurs in a minority. Hypothalamic damage occasionally leads to diabetes insipidus, disturbance of sleep rhythm or precocious puberty in children.

Lorber (1961) followed the long-term results in 100 children who survived the acute illness. A large variety of sequelae were seen but the number of children seriously affected was surprisingly small. Of this group, 77 had made a complete recovery, including some with very severe neurological abnormalities during the active phase of the illness; 23 showed defects in the form of paresis, fits, deafness or blindness, sometimes with gratifying improvement over time.

Fits persisted in only eight children despite their frequency in the acute stages. Six of the 23 were profoundly mentally retarded; all of these had been under 2 years of age and severely affected when first seen, and all had major neurological sequelae. Details of treatment are fully described in an excellent review by Thwaites and Hien (2005).

Cerebral abscess

Cerebral abscesses can present with remarkably few definite signs and symptoms. Headache may be slight and intermittent but is the most common reported symptom in those able to provide a history, papilloedema is often late, focal cerebral signs can be minimal and pyrexia tends to be absent in the chronic stage. It is essential therefore to consider the diagnosis when change of temperament or mild confusion is accompanied by evidence of ill health for which no immediate cause is obvious. In a retrospective series of patients seen at Atkinson Morley Hospital for neurosurgical interventions for brain abscess, Carpenter *et al.* (2007) found that psychiatric symptoms, and particularly confusion with or without alteration of conscious level, was present from the start in 51% of cases, only closely followed by headache in 49%.

Cerebral abscess is rarely seen without a focus of infection elsewhere, although this may be well concealed. Important sources near the brain include infection of the middle ear and mastoid cells, dental infections and extension from the frontal and sphenoidal sinuses. Head injury may convey infection by direct penetration or may open up pathways from the sinuses or ear when the base of the skull is fractured. The principal extracranial source is chronic suppurative disease of the lungs and pleura: bronchiectasis, lung abscess and empyema. Less commonly the abscess results from a general pyaemic infection caused by pelvic or abdominal suppuration, osteomyelitis, boils, cellulitis or subacute bacterial endocarditis. Paradoxical embolism of infected material may occur via septal defects in patients with congenital heart disease. With extracranial sources the abscesses are often multiple. In some 20–30% of cases the extracerebral source of the abscess remains unclear (Mathiesen & Johnson 1997).

The organisms chiefly responsible are streptococci, staphylococci or *E. coli*. The developing abscess arises from an area of suppurating encephalitis that becomes progressively walled off from the surrounding brain by a fibrous and glial reaction. Inflammation of the overlying meninges varies in severity with the activity of the lesion. The abscess may grow large, with distortion and compression of surrounding brain structures, but intracranial pressure may be little disturbed because the process is so gradual.

Classic, though rarely demonstrated, symptoms are headache, vomiting and mild delirium, but these may often be submerged in the symptoms of the predisposing infection. Alternatively, the abscess may remain quiescent at the time

of the original infection, and a latent interval of many months may follow before symptoms are declared. In the interim the patient shows evidence of chronic ill health: intermittent headache, malaise, loss of appetite and weight, constipation, occasional chills, depression and irritability. Ultimately, more definite signs appear, sometimes closely simulating cerebral tumour. Headache intensifies and may be paroxysmal, evidence of toxæmia increases, fits may occur and focal neurological signs are declared.

The common temporal lobe abscess is usually derived from middle ear infection. Motor signs are often very slight, and careful testing of the visual fields may be needed to display the quadrantic hemianopia. Dysphasic symptoms may be detected with abscesses of the dominant lobe. The alternative route from the middle ear is to the cerebellum. Signs can again be slight, with nystagmus, hypotonia and incoordination of the ipsilateral limbs, or cranial nerve pareses from involvement of the nearby brainstem. Frontal lobe abscesses arise from sinus infection or frontal fracture, and may lack all focal signs apart from unilateral anosmia. Concentration and memory may be markedly impaired and personality change much in evidence. In all such cases signs of raised intracranial pressure can be slight or absent, even with very large abscesses, and papilloedema may be late.

Some degree of aseptic meningitis may produce obvious neck stiffness on examination. Examination of the CSF rarely helps diagnosis and can be fatal if intracranial pressure is increased. CT has revolutionised the diagnosis of cerebral abscess, locating the abscess and allowing determination of its size and mass effect and whether the ventricles have been breached by the lesion (Moorthy & Rajshekhar 2008). The abscess is revealed after scan enhancement and has a characteristic appearance: the capsule shows as a ring-shaped area of increased density surrounded by cerebral oedema. MRI appearances are often specific enough for exact diagnosis – the capsule forming a discrete isointense or hyperintense ring surrounding a central cavity (Sze & Zimmerman 1988). Nonetheless, MRI is rarely necessary for diagnosis in preference to CT, other than in identifying the early cerebritis stages of abscess formation.

Treatment of cerebral abscess involves aspiration and excision followed by antibiotic therapy (Bernardini 2004; Moorthy & Rajshekhar 2008). With modern management the mortality has fallen progressively and the success rate for treatment is around 90%. Some degree of permanent incapacity may nonetheless persist, and epilepsy is liable to develop in up to 70% of cases. Intraventricular rupture and low initial Glasgow Coma Scale score are associated with poor outcomes (Takeshita *et al.* 1992).

Other infective processes

Acute organic reactions may accompany many systemic infections, especially at the extremes of life. An obvious

example is the delirium sometimes seen with the acute exanthemata of childhood, likewise the impairment of consciousness or delirium that occurs with pneumonia in the elderly. Slater and Roth (1969) discuss the various causes which may be operative. Cerebral anoxia often appears to be responsible, or the influence of toxins derived from the infecting microorganisms. More complex metabolic disturbances or the accumulation of toxic intermediate products must sometimes be postulated. Fever itself may play a direct part.

However, in the infections considered below, there is more definite evidence of cerebral involvement by the disease process itself. The conditions are dealt with briefly, and textbooks of general medicine should be consulted for further details.

Lyme disease

Lyme disease is caused by the spirochaete *Borrelia burgdorferi*, which is transmitted to humans through tick bites. It occurs in several regions of the USA and Europe, and cases have recently been reported from the UK, especially the New Forest area. It can lead to cutaneous, neurological, arthritic and cardiac manifestations, although the course is usually benign and self-limiting. The clinical pictures encountered are described by Burgdorfer (1987), and British experience of the disease is summarised by Bateman and White (1990) and O'Connell (1995).

The tick bite is followed by a characteristic rash (erythema migrans), which develops after some days or weeks and is often the pointer to the diagnosis. This consists of a spreading annular erythema that extends slowly outwards, usually on the trunk or limbs. It may be accompanied by systemic disturbances such as fever, headache or backache.

Neurological manifestations develop in some 15% of cases during the ensuing weeks or months, or can be the presenting feature. Eight cases from the New Forest region were described by Bateman *et al.* (1988). Some show a chronic low-grade meningitis with persistent headache and dizziness, others intense burning radicular pains and/or lower motor neurone facial palsies (Bannwarth's syndrome). Focal neurological signs and seizures may indicate brain parenchymal involvement. Complete recovery is the rule, though cases of chronic progressive encephalomyelitis have been reported in Europe and a syndrome resembling multiple sclerosis in the USA. Occasional patients are left with chronic fatigue and sometimes mild neuropsychological impairments. Recurrent attacks of arthritis may affect both large and small joints, and a transient myocarditis may occur, but these have been rare in the UK.

When the diagnosis is suspected, serological tests for antibodies to *B. burgdorferi* should be carried out (O'Connell 1995). False negatives and false positives can occur, but rising titres over several weeks may give definitive evidence of the infection. The results may be positive in the CSF when the serum is negative, so lumbar puncture should be performed

when there are neurological manifestations. The CSF shows pleocytosis with raised protein levels and often oligoclonal bands. The presence of borrelial DNA may be detected by PCR.

Treatment consists of penicillin or tetracycline and should be given promptly once the skin rash is detected. In the presence of neurological complications penicillin must be given parenterally, and cefotaxime may be required (Muhlemann 1992).

Typhus fever

Of the several varieties of typhus, that due to *Rickettsia prowazekii* is the most common. Epidemics are intimately associated with famines and wars and the infection is transmitted by the body louse. Mental and neurological manifestations are usually prominent, and there is abundant evidence that the causative organism invades the nervous system directly. The rickettsiae invade the endothelial cells of small blood vessels, producing foci of thrombosis and necrosis in various organs including the brain. Characteristic 'typhus nodules' consist of perivascular accumulations of glial, endothelial and phagocytic cells.

Symptoms consist of pyrexia, delirium, malaise, severe headache, cough and generalised aching. A characteristic rash appears on the fifth day of fever. More definite nervous system manifestations appear towards the end of the febrile period and are of serious import. Headache becomes continuous and periods of delirium alternate with stupor or coma. Focal signs appear in the form of hemiplegia, ataxia, bulbar dysfunction, deafness or optic neuritis. Meningeal irritation is common and the CSF shows a lymphocytosis and increased globulin. Among survivors evidence of cerebral damage frequently persists.

Trypanosomiasis (sleeping sickness)

The South African forms of trypanosomiasis are due to the protozoans *Trypanosoma brucei gambiense* and *T. brucei rhodesiense*. They are transmitted by the bite of the tsetse fly. An initial febrile stage consists of bouts of pyrexia, asthenia, adenitis, rashes and hepatosplenomegaly. This merges into the sleeping sickness stage, which is essentially a chronic meningoencephalitis with the organisms appearing in the CSF. The patient develops tremors, fits, incoordination or hemiplegia. Mental disturbances are prominent, with somnolence, apathy and eventually coma. Death usually occurs within a year if the disease is untreated.

Cerebral malaria

Delirium may be marked at the peaks of fever in any variety of malaria, but sometimes there is more acute and dramatic evidence of cerebral involvement. This is most common with infections due to *Plasmodium falciparum* (malignant tertian malaria). In fatal cases the brain is seen to be congested and oedematous, with numerous areas of haemorrhage and softening around vessels.

The cerebral capillaries are filled with parasites in various stages of development. The cerebral symptoms usually appear in the second or third week of the illness, but they may sometimes be the initial manifestation. They can be cat-alcysmic in onset. Severe delirium is accompanied by bursting headache and high pyrexia. The patient is often combative and excitable before coma supervenes. Fits can be the presenting feature and focal signs are common: hemiplegia, dysphasia, hemianopia or cerebellar ataxia. Retinal haemorrhages and papilloedema may occur.

The picture can simulate encephalitis, meningitis, cerebral tumour, epilepsy, cerebrovascular lesions or a variety of acute psychiatric disorders (Boshes 1947). Mistakes are particularly likely to be made in the rare examples when the patient is afebrile. Nadeem and Younis (1977) also stressed that clouding of consciousness may be absent initially. Of 39 patients admitted to a Sudanese psychiatric hospital with mental illness precipitated by physical disease, 17 proved to have malaria. Half of these showed psychiatric disturbances in clear consciousness. Thus where malaria is endemic it must be borne in mind in all patients with psychoses of acute onset, whether or not organic features are evident in the mental state.

Rapid treatment is vital, so examination of blood smears must not be delayed in suspected cases. Care must be taken to enquire about countries in which the patient may have lived or travelled whenever an acute organic reaction occurs without obvious cause. The number of cases reported in the UK has increased substantially over the years as a result of visits by businessmen and back-packers to heavily infected regions (Wyatt 1992).

Cerebral cysticercosis

The cysticercus stage of the tapeworm, usually *Taenia solium*, may occur in humans. Common sites include the skeletal muscles and the brain. The infestation is extremely common in Mexico. McCormick *et al.* (1982) and Grisolia and Wiederholt (1982) describe the typical clinical pictures.

Multiple cysts are usually present within the brain and the main damage appears to occur when the larvae begin to die. There is then an intense inflammatory reaction in an attempt to wall off the irritating process. The circulation of the CSF is often obstructed.

The usual presentation is with focal seizures, or with symptoms of raised intracranial pressure due to internal hydrocephalus. Localising signs are relatively uncommon, though sudden neurological deficits can result from infarcts. Very occasionally dementia is the presenting feature. Retinal involvement may accompany the CNS disturbance.

The CSF shows a pleocytosis including eosinophils, an increase in protein and a positive reaction to serological tests for cysticercosis. However, the latter may be negative in up to 40% of patients (McCormick *et al.* 1982). Calcification of the cysts may be seen on radiography, both within the skull

and in the skeletal muscles. Neuroimaging is valuable in revealing the lesions or the resulting hydrocephalus when skull radiography is negative.

Plate 2.1 Representative slices from VLSM maps computed for fluency and auditory comprehension performance of 101 aphasic stroke patients.

These maps are coloured depictions of t -test results evaluating patients' performance on a voxel-by-voxel basis, for fluency (a–c) or

auditory comprehension (d–f). High scores (red) indicate that lesions to these voxels have a highly significant effect on behaviour. Dark blue voxels indicate that the lesions had relatively little impact on behaviour. From Bates *et al.* (2003), *Nature Neuroscience* **6**, 448–450. See also Fig. 2.1.

Plate 2.2 Brain regions in which significant volume deficits in patients with schizophrenia were reported in voxel-based morphometry studies ($N=15$), by percentage of studies reporting the deficit. In row (a), left and right whole-brain three-dimensional images are overlaid with all regions in which significant volume

deficits in patients with schizophrenia were reported. In row (b), a coronal view and an axial three-dimensional image are shown. In row (c), axial views are shown. From Honea *et al.* (2005), *Am J Psychiatry* **162**, 2233–2245. © 2005 American Psychiatric Association. See also Fig. 2.2.

Plate 3.1 Coronal magnetic resonance brain images illustrating different scanning sequences (see also Fig. 3.5). T1, inversion recovery; T2, spin-echo; PD, proton density. (Courtesy of Dr Nancy Andreasen.)

Plate 3.2 Serially acquired T1-weighted MRI scans from an initially asymptomatic patient destined to develop familial Alzheimer's disease. Scans were acquired over 4 years before criteria for dementia were met; the first symptoms were reported between scans (d) and

(e). Each scan has been positionally registered to the baseline scan; red overlay represents tissue loss compared with baseline. See also Fig. 3.10. (From Fox & Schott 2004 with permission.)

Plate 3.3 Functional magnetic resonance imaging: differences in relative language lateralisation for a verbal fluency task can be found between patients with right or left temporal lobe epilepsy (TLE). Illustrative activation maps are shown here, co-registered with individual high-resolution structural MRI. Cluster detection was done on all voxels above $z = 2.3$ to determine clusters significantly

activated (corrected $P < 0.01$) in the experimental task condition. The patient with right TLE has predominantly left hemisphere activation. In contrast, the activation map for the patient with left TLE shows bihemispheric activations. See also Fig. 3.15. (From Matthews & Jezzard 2004 with permission.)

Plate 3.4 Fluorodeoxyglucose positron emission tomography images in Alzheimer's disease: (left) normal brain; (right) Alzheimer's brain. Arrows point to area of posterior hypometabolism. See also Fig. 3.16. Available at http://www.uhseastpetscan.com/zportal/portals/pat/brain/Alzheimers_Disease/pet_scans

Plate 3.5 Striatal uptake of dopamine transporter (DAT) ^{11}C -RTI-32, ^{123}I - β -CIT, $^{99\text{m}}\text{Tc}$ -TRODAT, vesicular monoamine transporter (VMAT2) ^{11}C -DTBZ, and dopa decarboxylase (DDC) ^{18}F -dopa in a healthy control subject and a patient with early Parkinson's disease (PD). In PD the putamens are targeted asymmetrically. See also Fig. 3.17. (From Brooks & Piccini 2006 with permission.)

Plate 3.6 An HMPAO-SPECT scan from a normal subject, using a Strichman Medical Equipment multislice, head-dedicated scanner. The slices are orientated parallel to the orbitomeatal plane. See also Fig. 3.18. (Courtesy of the Department of Nuclear Medicine, King's College Hospital, London.)

Plate 7.1 Large multinucleated giant cells in cerebral white matter of a patient with HIV encephalitis and dementia (see also Fig. 7.2). Haematoxylin and eosin, magnification $\times 250$. (Courtesy of Dr Ian Everall.)

Plate 7.2 A multinucleated giant cell from a patient with HIV encephalitis immunostained for the glycoprotein gp41 revealing viral particles (see also Fig. 7.3). Magnification $\times 400$. (Courtesy of Dr Ian Everall.)

(a)

(b)

Plate 9.1 (a) Neuritic plaque and (b) neurofibrillary tangles (see also Fig. 9.1).

Plate 11.1 Key elements of the neurocircuitry of addiction (see also Fig. 11.1). (From Koob *et al.* 2008 with permission.)

Plate 12.1 Lewy bodies in the substantia nigra (haematoxylin and eosin). Magnification $\times 600$. (Courtesy of Professor Peter Lantos.) See also Fig. 12.1.

Cerebrovascular Disorders

Simon Fleminger

Maudsley Hospital, London

Diseases of the vascular system contribute greatly to the sum total of psychiatric disability, chiefly in the elderly population and mainly as a result of stroke. Strokes, cerebrovascular accidents and subarachnoid haemorrhage are therefore considered first, with emphasis on their psychiatric sequelae and the problems encountered in rehabilitation. Over recent years much has been learnt about the biological basis of migraine and this important common condition is considered next. Finally, certain diseases of rather obscure aetiology, such as systemic lupus erythematosus and other forms of vasculitis, are described. The psychiatric components of such illnesses have gained increasing recognition and appear to be attributable in part to involvement of the cerebral vasculature.

Stroke

Strokes are the third commonest cause of death after heart disease and cancer in the Western world. The incidence of a first stroke is about 2 per 1000 per year (Bamford *et al.* 1988) and it has been estimated that almost one in four men and one in five women aged 45 can expect to have a stroke if they live to 85 (Bonita 1992). Therefore, in a population of 250 000 (the basis for a district general hospital) more than 500 strokes will occur per annum, of which about 150 will be added to the accumulating number needing continuing care (Hurwitz & Adams 1972). As a result, stroke is probably the most frequent cause of severe disability in the community (Harris *et al.* 1971). Moreover, approximately one-quarter of victims affected are under 65 years of age and are thus disabled during the productive years of their lives.

The principal causes of stroke are atherosclerosis and hypertension. Among predisposing causes, factors susceptible to modification include hypertension, heart disease, diabetes, raised serum lipids and smoking. Severely threatening life events may be commoner in stroke victims than controls throughout the year preceding the stroke (House *et al.* 1990).

There is new interest and vigour in solving the problems of rehabilitating survivors, although psychiatrists are often little involved in the process. This is disappointing, in that much of the disability resulting from strokes is mental rather than physical, and psychological influences can be paramount in determining what progress is made. In what follows, the general background to cerebrovascular accidents is briefly sketched before reviewing what is known of the psychological and psychiatric aftermaths.

Classification of stroke

Older definitions of stroke have tended to demand that symptoms should have lasted more than 24 hours, partly in order to distinguish stroke from transient ischaemic attacks. However, such definitions are less valuable now that very early interventions, within the first 3 hours of onset, may need to be implemented in patients who are nevertheless probably going to develop permanent symptoms. In practice any recent disturbance of cerebral function meeting the criteria described in Box 8.1, and with no apparent cause other than a vascular origin, should be regarded as a stroke.

There are two essential pathological processes underlying stroke: infarction (ischaemia) and haemorrhage. Infarction is commoner than haemorrhage by a ratio of approximately 4:1. It is not only more frequent as an acute development but very much more so as a source of enduring disability. Thus approximately three-quarters of patients with infarctions survive, whereas almost two-thirds of patients with cerebral haemorrhage die within a year (Bamford *et al.* 1990). Infarction may result from thrombosis of vessels or from emboli which come to lodge within them. Haemorrhage may be primarily into the substance of the brain or into the subarachnoid space. Hypertension is a risk factor for both cerebral infarct and haemorrhage, although the strength of the association is greater for haemorrhage (Song *et al.* 2004).

Box 8.1 Criteria for diagnosing stroke (Warlow *et al.* 1996)

A stroke should be suspected when:

- there is a sudden onset of symptoms
- focal symptoms and signs are present that can be explained by a single lesion of the brain
- there is loss of function
- symptoms and signs are maximal at onset, then remain stable or improve over time

However, on occasion:

- symptoms may develop over a few minutes
- symptoms may not be explained by a single lesion, e.g. there has been previous stroke
- symptoms may be 'positive', e.g. jerking, paraesthesiae, visual hallucinations
- symptoms may have a sudden onset and then worsen over minutes or hours

Cerebral haemorrhage

Intracranial haemorrhage, representing some 15% of all strokes, may be divided into subarachnoid haemorrhage from a ruptured cerebral artery aneurysm and primary intracerebral haemorrhage. The differentiation is not always absolute, since bleeding may occur into brain tissue in the neighbourhood of a ruptured aneurysm, and blood may gain access to the ventricular system and subarachnoid space after primary intracerebral haemorrhage. Subarachnoid haemorrhage is dealt with later in this chapter.

Primary intracerebral haemorrhage is most common in patients between the ages of 60 and 80 and is usually associated with hypertension, particularly in younger patients, for example in their forties or fifties. The precise mechanism whereby haemorrhage develops continues to be the subject of controversy. Deep haemorrhages, into basal ganglia, thalamus, pons and cerebellum, are regarded as more closely associated with hypertension than are lobar haemorrhages into temporal, frontal, parietal or occipital lobes. It has been proposed that lipohyalinosis of the small penetrating arteries due to hypertension may result in deep intracerebral haemorrhage or lacunar infarcts (Jackson & Sudlow 2006). On the other hand, in lobar haemorrhage, particularly in the elderly, cerebral amyloid angiopathy, with deposition of congophilic amyloid- β protein in cerebral cortical and leptomeningeal vessels, may be the main pathological process (Labovitz & Sacco 2001).

Comparing groups of patients it is possible to demonstrate differences between the clinical presentation of those with cerebral haemorrhage compared with those with cerebral infarct. For example, in intracerebral haemorrhage the onset is often during exertion and rarely during sleep as with cerebral infarct. Headache, vomiting and loss of consciousness are more common with haemorrhage. However, these differ-

ences are not specific enough to allow a diagnosis at the individual level. For this purpose it is essential to perform computed tomography (CT) of the brain, or magnetic resonance imaging (MRI) with appropriate T2* gradient echo Sequences, to identify acute haemorrhage. In practice neuro-imaging is required as soon as possible after presentation to determine if the stroke is due to an infarct, which can be treated with thrombolysis, or to haemorrhage, in which case thrombolysis is contraindicated.

Deep haemorrhage into basal ganglia and adjacent internal capsule will produce a dense contralateral hemiplegia and may be accompanied by deviation of the head and eyes away from the side of the lesion. The formation of a large intracerebral haematoma can lead to secondary effects due to tentorial herniation and brainstem compression. Another site of predilection is the cerebellum, leading to a similar picture but with vertigo and ataxia during the early stages. With haemorrhage into the pons consciousness is usually lost rapidly, the pupils are unequal or pinpoint, hyperpyrexia may occur and quadriplegia is likely to be present.

Early mortality is high, and survivors are usually severely disabled. However, mild examples with only brief loss of consciousness may make a reasonably good recovery. Medical treatment during the acute stages rests primarily on excellent nursing care.

Cerebral infarction

The two most widely used classifications of cerebral infarcts are based on aetiology or on location (Box 8.2). There is some degree of overlap between the two because for some causes of stroke there are areas of particular vulnerability. This is the case for small-artery occlusions (lacunar infarcts), which are localised to subcortical structures and brainstem. It has been estimated that about 50% of ischaemic strokes (infarcts) are due to large-artery atherosclerosis, 25% to lacunar infarcts and 20% to cardiac embolism, with only 5% due to rarer causes (Davenport & Dennis 2000).

Large-artery atherosclerosis may result from cerebral thrombosis or local emboli, the two often being difficult to distinguish clinically. Lipid material accumulates beneath the intima of affected vessels and as the plaques thicken the lumen narrows and thrombus may form. The vessels chiefly involved are the aorta, carotid arteries, middle cerebral arteries and vertebrobasilar arteries. The occlusion may result from local thrombus formation within the stenotic vessel or thromboemboli from proximal arteries. In some a transient fall in blood pressure, as after myocardial infarction, further compromises flow in vessels already critically affected and precipitates the thrombosis. The size of the infarct will depend on the vessels principally involved and also on the efficiency of the collateral circulation. The result is often a total anterior circulation infarct (TACI).

Cerebral small-vessel disease of the small penetrating arteries supplying the basal ganglia, thalamus, internal capsule

Box 8.2 Classification of cerebral infarcts**By cause** (Adams *et al.* 1993)**Large-artery atherosclerosis**

- Thrombosis and/or embolism related to stenosis or occlusion of a major brain artery or branch cortical artery
- A history of intermittent claudication, transient ischaemic attacks (TIAs) in the same vascular territory, a carotid bruit or diminished pulses supports the diagnosis
- Need to exclude cardiac emboli

Cardioembolism

- Arterial occlusions presumed due to emboli from the heart
- Evidence of TIAs in more than one territory, or systemic emboli support the diagnosis
- High-risk sources include mitral valve stenosis, prosthetic valve, atrial fibrillation, myocardial infarct within 4 weeks, dilated cardiomyopathy and atrial myxoma

Small-artery occlusion, lacunar infarcts

- Presents with lacunar syndrome
- Normal CT/MRI or subcortical lesion less than 1.5 cm diameter
- Diagnosis supported by presence of hypertension

Stroke of other aetiology

- Non-atherosclerotic vasculopathy, hypercoagulable states, arterial dissection, haematological disorders, fat emboli

Stroke of undetermined aetiology**By location** (Bamford *et al.* 1991)**Total anterior circulation infarcts**

- Large anterior circulation infarcts with both cortical and subcortical involvement. Hemiplegia plus hemianopia plus aphasia or visuospatial neglect
- Worst prognosis: 60% dead and 4% independent at 1 year

Partial anterior circulation infarcts

- Predominantly cortical infarcts. More localized cerebral deficit, e.g. aphasia or visuospatial neglect or motor or sensory deficit or hemianopia
- Most likely to have early recurrent stroke

Posterior circulation infarcts

- Associated with vertebrobasilar arterial territory. Ipsilateral cranial nerve deficit plus contralateral motor or sensory deficit or cerebellar signs
- High recurrence rate throughout first year

Lacunar infarcts

- Confined to the territory of the deep perforating arteries. Pure motor hemiparesis or hemisensory deficit
- Best prognosis: 11% dead and 60% independent at 1 year

or pons causes lacunar infarcts (Fisher 1982) and/or white matter changes. As noted above, lipohyalinosis of the vessel wall may be found and hypertension is an associated finding in the majority of cases. Lacunar infarcts may be multiple and almost microscopic in size. Leucoaraiosis describes the presence of multiple lesions in the deep hemispheric and periventricular white matter seen on neuroimaging. Both lacunar infarcts and leucoaraiosis are probably due to endothelial dysfunction associated with breakdown of the blood–brain barrier, harmful leakage into the perivascular spaces, and impaired autoregulation (Hassan *et al.* 2003; Wardlaw 2005) in and around the small penetrating arteries, for example the lenticulostriate arteries. Cerebral microbleeds may be seen on gradient echo MRI (Werring *et al.* 2005).

Cardiac emboli should be suspected when there is atrial fibrillation, mitral stenosis, subacute bacterial endocarditis or a recent myocardial infarction. Rare forms include paradoxical embolism, in which a congenital cardiac malformation allows material from the veins of the legs to reach the brain by bypassing the pulmonary circulation.

The clinical picture in cerebral thrombosis usually develops abruptly, though less so than with embolism. Occasionally the development is insidious, with the neurological deficit increasing over hours or days and progressing in a stepwise or saltatory fashion. Onset is often during sleep. In cerebral embolism, whether cardiac or from the large vessels, the clinical picture is usually extremely acute in onset, developing within seconds or a minute and often during activity. The neurological deficit is typically maximal from the outset, often with rapid resolution over the first few hours thereafter. Regardless of the cause of the cerebral infarction, headache may be present in the early stages but is often absent throughout. Some degree of mental confusion is common, but consciousness may be little if at all impaired. However, large infarcts may be followed by swelling of the affected hemisphere, leading to coma. Coma following infarcts of the posterior circulation is due to direct effects on brainstem pathways involved in maintaining conscious level.

The prognosis for cerebral infarction is much better than for cerebral haemorrhage. Approximately 20% of patients die in the acute stage, 20% recover completely and 60% are left with residual disability. Recovery from emboli is in general much quicker and more complete than after thrombosis, since collateral channels will usually be more readily available. In both, however, much will depend on the size of the infarct produced.

Cerebral arterial syndromes

Occlusion of the proximal stem of the *middle cerebral artery* will usually lead to a TACI (see Box 8.2), with ischaemia in both the deep and superficial territories of the middle cerebral artery (Bamford *et al.* 1991). A TACI is defined by the presence of a contralateral hemiparesis or sensory deficit

plus hemianopia (due to involvement of the optic radiation) plus a disorder of higher cortical function. The latter, dependent on which hemisphere is affected, may be a dysphasia, agnosic syndrome, or body image disturbance with visuo-spatial neglect. In some cases of TACI, the anterior cerebral artery is also involved.

Partial anterior circulation infarct may be seen if more distal parts of the middle cerebral artery are affected or with isolated occlusions of the anterior cerebral artery. More localised disturbance including weakness mainly involves the face, arm and hand, or an isolated disorder of higher cortical function is found after distal occlusion of branches of the middle cerebral artery. Infarctions in the distribution of the *anterior cerebral artery* lead to contralateral hemiparesis affecting the leg more severely than the arm. There may be a grasp reflex in the hand. Cortical sensory loss and motor dysphasia are often present as well. Mental changes may resemble those of a global dementia and incontinence may be a prominent feature. Residual personality changes of frontal lobe type may occur.

Mesulam *et al.* (1976) drew attention to the states of mental confusion that can follow middle cerebral infarctions on the right, sometimes leading to diagnostic difficulties in that focal signs may consist of little more than left-sided cortical sensory loss and visual inattention. A toxic or metabolic cause for the acute organic reaction had often been suspected in their patients. Salient features were inattentiveness to relevant stimuli and inability to maintain a coherent stream of thought or behaviour. Disorientation, anomia, incontinence, an abnormal gait and lack of concern for the illness were characteristic. An example follows.

A 61-year-old man was discovered in an incoherent agitated state, banging on doors and shouting in the night. He was disoriented in all spheres, very distractible, and with a severely diminished span of attention. His speech contained paraphasic errors and there were difficulties in naming objects. Gait was unsteady and he was incontinent and unkempt. Over the next few days the agitation gave way to an amiable placid state, but the incoherence and impaired attention span persisted for several weeks. Angiography showed occlusion of the right angular branch of the middle cerebral artery (Mesulam *et al.* 1976).

A common tell-tale sign of occlusion of the *internal carotid artery* is monocular blindness, fleeting or permanent, in the eye contralateral to hemiplegia, due to interruption of blood flow in the ophthalmic or retinal arteries. However, internal carotid artery occlusion can be entirely asymptomatic, emerging as a chance finding at post-mortem. If the circulation should fail, infarction occurs principally in the territory of the middle cerebral artery, although the distribution of the

anterior cerebral artery may be involved as well. Much depends on the efficiency of the collateral circulation and the patency of the circle of Willis.

Border-zone infarcts, otherwise known as watershed infarcts, occur at the boundary between adjacent arterial territories (Fig. 8.1). *Internal border-zone infarcts* are subcortical and occur where the territories of the deep penetrating branches (Heubner, lenticulostriate and anterior choroidal arteries) of the major cerebral arteries meet the cortical branches of the anterior, middle and posterior cerebral arteries (Donnan *et al.* 1993). *Cortical border-zone infarcts* occur at the boundary between the territory of the middle cerebral artery and the anterior and/or posterior cerebral artery; they occur in a sickle-shaped zone on the lateral surface of the hemisphere (Fisher 1968), with the junction between the parietal and occipital lobes being particularly vulnerable. The border-zone area is vulnerable because it is at the limits of perfusion of the arteries supplying the two adjacent areas. Therefore under conditions of reduced blood flow, for example due to severe systemic hypotension, these areas will be the first to suffer ischaemia. Border-zone infarcts are associated with internal carotid artery stenosis or occlusion, but emboli thrown off from behind and around the stenosis may be as important as the haemodynamic effects of the stenosis (Barnett 1997). It has been proposed that a healthy perfusion pressure can wash out emboli, particularly microemboli, and therefore 'impaired washout is an important but neglected concept that intertwines hypoperfusion, embolization, and brain infarction' (Caplan & Hennerici 1998).

The resulting clinical picture of border-zone infarcts is varied and often indistinguishable from that of middle cerebral infarction. Occasionally, an isolated agnosia, visual or auditory, is seen with an infarct in the zone between middle and posterior cerebral arteries. Sometimes mental symptoms may predominate with general slowing, decreased spontaneous activity, dyspraxia and incontinence, all pointing to a frontal lobe deficit. If the abruptness of onset and fluctuation in the symptoms is not appreciated, the nature of the lesion may not be detected, as in the following example reported by Fisher (1968).

A man of 68 had shown a change of personality for some 4 months, consisting of selfishness, overeating and impoliteness, combined with clumsiness, falling, spilling food, episodic difficulty in speaking and urinary incontinence. On examination he stared vacantly into space, spoke in a quiet voice, forgot quickly and was clumsy in all his movements. There were elements of dysphasia, both hands were dyspraxic, and he broke spasmodically into tears. Angiography showed left carotid occlusion but this was felt to be irrelevant. He died suddenly and post-mortem revealed an extensive watershed infarct in the left hemisphere.

Fig. 8.1 Territories of the major cerebral arteries. (From Del Sette *et al.* 2000 with permission.)

Almost half of *posterior cerebral artery* strokes are due to cardiac emboli (Yamamoto *et al.* 1999; Cals *et al.* 2002). The main effect of posterior cerebral artery infarction is a contralateral hemianopia, sometimes with visual hallucinations, visual agnosias or spatial disorientation. Visual perseveration may consist of a train of objects repeating within the affected field, or persistence of an image in the centre of the field after the object is removed (Caplan 1980). Alexia without agraphia occurs when damage has affected the dominant occipital lobe along with the splenium of the corpus callosum (see Chapter 2, under Pure word-blindness). Bilateral infarctions may lead to cortical blindness, sometimes with conspicuous denial of disability (Anton's syndrome). Adams

and Hurwitz (1974) stressed that psychological disturbances are frequent with posterior cerebral infarctions. Transient mental confusion and agitation has been reported in 7% (Cals *et al.* 2002) to 40% (Ng *et al.* 2005). This may be the only manifestation apart from a hemianopia which is difficult to demonstrate. Amnesic syndromes may also figure prominently when the hippocampus and other limbic structures are involved bilaterally on the inferomedial surfaces of the temporal lobes (Victor *et al.* 1961; Benson *et al.* 1974). In those with unilateral lesions amnesia may be more common if the left hemisphere is involved (Cals *et al.* 2002).

The two posterior cerebral arteries are fed by the basilar artery, which is formed by the two vertebral arteries. From

the *vertebrobasilar system*, perforating branches supply the brainstem and cerebellum. Infarctions in the territory of individual branches of the vertebrobasilar system can lead to a multitude of pictures. The hallmark is brainstem involvement, with bilateral or unilateral pyramidal signs and a variety of ipsilateral cranial nerve palsies. Ipsilateral cerebellar deficits may also be present. Major obstacles to recovery include disturbances of balance and persistent dizziness. Intellectual processes may be affected. In seven patients admitted to a rehabilitation unit with isolated brainstem lesions, five of which were infarcts, impaired attention and executive function was found although disturbance of memory was unusual (Garrard *et al.* 2002). Subtle impairments of cognitive function may be seen even in those with small isolated lacunar infarcts of the brainstem (van Zandvoort *et al.* 2003). These findings have been confirmed in a large series of subtentorial strokes which found that executive impairment was common, regardless of whether the stroke involved the brainstem or cerebellum (Hoffmann & Schmitt 2004).

Total occlusion of the basilar artery is usually rapidly fatal, with loss of consciousness, a decerebrate state and quadriplegia. The various pictures of coma, decerebration and akinetic mutism that may follow brainstem infarction are described by Plum and Posner (1972). One rare but striking picture is the so-called 'locked-in' syndrome which follows a circumscribed infarction affecting the descending motor pathways in the ventral part of the pons. This is compatible with full wakefulness and alertness, despite aphonia and total paralysis of the limbs, trunk and lower cranial nerves. Such patients are responsive and sentient but may only be able to communicate using blinking and eye movements. In a survey of carers of 44 patients with locked-in syndrome, 38 due to brainstem stroke and six to trauma, the majority reported little if any problems with cognitive function, although memory problems were described in 18% (Leon-Carrion *et al.* 2002). These findings are consistent with more detailed neuropsychological testing in patients with locked-in syndrome who may (New & Thomas 2005) or may not (Allain *et al.* 1998) show evidence of impairment.

Caplan (1980) reviews further striking pictures with prominent behavioural change following occlusion of the rostral branches of the basilar artery ('top of the basilar' syndrome). The result is infarction in the midbrain, thalamus and portions of the temporal and occipital lobes, producing an array of visual, oculomotor and behavioural abnormalities often with changes in alertness and sleep-wake cycle. Motor dysfunction can be minimal, leading to difficulties with diagnosis. The remarkable syndrome of *peduncular hallucinosis* consists of vivid well-formed hallucinations, sometimes confined to a half-field of vision and occurring with or without visual field defects. The hallucinations are recognised by the patient as unreal despite their dramatic nature.

Caplan's patient saw a parrot in beautiful plumage to the right, and pictures of a relative flashed on the wall to the left. Others have reported vivid hallucinations of animals, of children at play with toys, fleeting images of the head of a dog or intricate lines and colours lasting for an hour or two at a time. States of *bizarre disorientation* accompanied by somnolence may likewise reflect disturbance in the rostral portions of the brainstem reticular formation. In response to questions one patient said she was lying on a beach at Nice, another that she was speaking to friends on the telephone. Such answers, entirely divorced from the current reality, may appear as an extraordinary form of confabulation. Other patients may dream excessively, with inability to distinguish the dreams from reality. Oculomotor disturbances and pupillary abnormalities will usually betray the origins of such abnormal mental states.

The diverse cognitive and behavioural effects of thalamic infarcts, which can partly be explained by which thalamic nuclei are involved, have recently been reviewed (Carrera & Bogousslavsky 2006). Confusion and altered conscious level are often early manifestations. Personality change, particularly disinhibition and apathy, executive difficulties often with perseveration, and occasionally psychotic mood change may follow. Amnesic syndromes may be seen as well as aphasia or visuospatial neglect. Central pain may be more common after right-sided thalamic lesions (Nasreddine & Saver 1997). Quite often both paramedian thalamic nuclei are supplied by a single paramedian artery, which partly explains why bilateral thalamic infarcts are not all that uncommon (Schmahmann 2003).

Very small lacunar infarcts may be asymptomatic, but those 0.5–1.5 cm in diameter are likely to produce deficits (Fisher 1982; Gautier 1983). Lacunar infarcts do not result in any disturbance of higher cortical function or visual field deficit. Pure motor hemiparesis, due to lacunes in the posterior limb of the internal capsule or pons, hemisensory stroke, often with lacunes in the posterolateral thalamus, and ataxic hemiparesis (dysarthria clumsy hand syndrome or ipsilateral ataxia with crural hemiparesis) are seen. The deficits resulting from lacunar infarcts are usually slight and recover rapidly and the risk of death early after the stroke is relatively small. However, after several years 10% or more, particularly those with leucoaraiosis, will develop a vascular dementia (Norrvig 2003) (described in Chapter 9), sometimes accompanied by a pseudobulbar palsy.

Transient ischaemic attacks

The classic definition of a transient ischaemic attack (TIA) is acute loss of focal cerebral or monocular function that resolves completely within 24 hours, and with no other explanation for the symptoms than inadequate blood supply. This definition was introduced in an attempt to distinguish episodes that resulted in no permanent brain infarction from stroke. Most TIAs only last a few minutes and leave no per-

manent infarct. However, for episodes lasting between 4 and 24 hours the majority of patients will have evidence of brain infarction on diffusion-weighted MRI (Engelter *et al.* 1999). And, given that thrombolysis for stroke has to be given within about 3 hours of the onset of symptoms to be effective, the classical definition of TIA is no longer useful. TIAs are therefore now more usually defined as 'a brief episode of neurologic dysfunction caused by focal brain or retinal ischemia, with clinical symptoms typically lasting less than one hour, and without evidence of acute infarction' (Albers *et al.* 2002).

The feature common to all TIAs is temporary reduction of the blood supply to a small area of the brain, long enough to cause manifest but transient loss of function. Both stroke and TIAs can be considered as lying on a spectrum of outcomes from brain ischaemia (Albers *et al.* 2002), with atherothromboembolism, cardiogenic embolism and intracranial small-vessel disease probably accounting for 95% of cases (Bamford 2001). Many TIAs are probably caused by small emboli that temporarily occlude blood flow before breaking up (del Zoppo 2004). The emboli may consist of platelet aggregates, cholesterol or small fragments of thrombus. Emboli passing up the major vessels have been detected as high-intensity transient signals (HITS) on Doppler sonography (Markus *et al.* 1995), although in almost all cases such HITS are asymptomatic. Nevertheless, the presence of HITS may indicate an increased risk for TIA or stroke.

In occasional cases haemodynamic factors may be responsible. Thus a sudden fall in cardiac output, or systemic hypotension due to any cause, may compromise flow in vessels already critically narrowed by atherosclerosis. Anaemia or polycythaemia may be background factors facilitating the development of attacks.

TIAs in the carotid territory typically show contralateral pareses, paraesthesiae, hemianopias or dysphasia, sometimes with transient blurring or even episodes of total blindness in the ipsilateral eye (amaurosis fugax). Microemboli may actually be observed in the retinal arteries on ophthalmoscopy in such cases. Motor impairments may take the form of a brief monoparesis involving only part of a limb. Transient numbness of the face or arm is a common variety. Mental confusion may occasionally be marked but in general non-focal symptoms are absent. Vertebrobasilar TIAs present with a multitude of pictures. Spells of vertigo, tinnitus or diplopia are typical. Episodes of paresis or numbness may involve different sides of the body in successive attacks. Drop attacks are commonly attributable to such a cause in the elderly—the person falls abruptly to the ground without loss of consciousness, then can rise immediately—as a result of acute and transient failure of the antigravity muscles. Sometimes a staggering ataxia may be combined with dysarthria and drowsiness, leading to an impression of drunkenness. Visual phenomena include blurred vision, altitudinal or homonymous hemianopias, or scintillation scotomata.

Box 8.3 Differential diagnosis of transient ischaemic attack

- Migraine aura
- Structural brain lesion (subdural, intracranial tumour, aneurysm, intracranial haemorrhage, sinus thrombosis)
- Postictal deficit (e.g. Todd's paresis)
- Epilepsy
- Hypoglycaemia
- Simple faint
- Labyrinthine disease
- Multiple sclerosis
- Transient global amnesia
- Cerebral infection
- Panic attack

Transient bilateral blindness may occur where both posterior cerebral arteries are implicated.

Because TIAs are associated with significant morbidity in the days and months that follow, accurate identification is important; several differential diagnoses need to be considered (Box 8.3). One-tenth of patients will have a stroke within 90 days and one-quarter within 5 years; 20% will have had a stroke or myocardial infarct or be dead by 1 year. Those at greatest risk of later stroke have longer-lasting TIAs, repeated TIAs while receiving antiplatelet therapy, or have crescendo TIAs (more than three events in 3 days of increasing severity, duration or frequency). Other high-risk factors for subsequent stroke include having a cardioembolic source, being over 60 years of age, and having diabetes mellitus or hypertension. Weakness or speech impairment during the episode also increases the risk (Shah & Edlow 2004). Investigations will therefore be aimed at identifying risk factors for subsequent stroke, and the cause of the TIA. Investigations are likely to include a full blood screen, ECG, echocardiography and, depending on the territory involved, carotid Doppler sonography. MRI with diffusion-weighted imaging is the best way of determining if there is any evidence of brain infarction.

Once neuroimaging has excluded the possibility of an intracerebral bleed, antiplatelet agents (e.g. aspirin or clopidogrel) are the mainstay of medical management. Anticoagulation has no value unless there is clear indication of a cardiac source of emboli, for example atrial fibrillation, prosthetic heart valve or recent myocardial infarct. Carotid endarterectomy has an important role in the prevention of later infarction in patients with greater than 70% stenosis of the carotid artery (Barnett *et al.* 1998).

Neuroimaging of stroke

The acute management of stroke, within the first few hours of onset, goes hand in hand with neuroimaging protocols,

developed over the last few years, designed to help the clinician decide whether intravenous thrombolysis is indicated (Masdeu *et al.* 2006). Having confirmed that the neuroimaging findings are indeed those of a vascular lesion, the first priority is then to separate haemorrhagic stroke, in which case thrombolysis is contraindicated, from ischaemic stroke. Subsequently, assessment of the extent of ischaemic but salvageable brain (the penumbra) around the core of non-viable tissue may improve selection of those most likely to benefit from thrombolysis. Neuroimaging may also help identify the cause of the stroke, for example picking up multiple cortical infarcts suggestive of cardiac emboli.

In the acute stage, infarcts of the major cerebral arteries are considered to produce three zones of hypoperfused tissue (Muir *et al.* 2006). The *core* of the infarct, where the opportunity for anastomotic perfusion is least, is defined as the zone where cells will inevitably die. Within the core there may be a zone where only neurones die, surrounding a zone where the ischaemia is so severe that no cell, including glial elements, has a chance of survival. The *penumbra* is the ischaemic zone surrounding the core and is defined as the zone where tissue may either die or survive in the long term. Here the blood flow is about 10–20 mL/min per 100 g. The consequent ischaemia impairs neuronal function, giving rise to neurological symptoms over and above those arising from neuronal death in the core. Finally, surrounding the penumbra is a zone of *oligaemia*, with blood flow greater than 20 mL/min per 100 g but less than the normal value of about 50 mL/min per 100 g, where oxygen extraction is increased, neuronal function is maintained and cell death in the long term is unlikely.

In the acute stage the size of the core determines the extent to which there will be inevitable permanent damage, whereas the size of the penumbra indicates the potential for recovery and for thrombolysis to salvage brain tissue. Therefore identifying the extent of these zones, using neuroimaging, is clinically useful. CT of the brain is quick, generally more accessible than MRI, and detects any early significant intracerebral haemorrhage; by about 10 days any haemorrhage loses its high signal on CT and becomes isodense with brain and is therefore more easily missed. Within the first 3 hours of onset of the stroke, CT brain scan is generally used as part of the protocol to determine if a patient is suitable for thrombolysis (Masdeu *et al.* 2006). However, CT is not as sensitive as MRI for the detection of stroke. In the acute stages a severe stroke can be surprisingly difficult to detect on CT, although detection rates can be improved when the image is systematically examined for early signs of stroke (Barber *et al.* 2000). CT perfusion, which involves tracking an intravenous bolus of contrast media as it passes through the brain, may be used as an alternative to MRI (see below) for identifying the penumbra.

MRI has greater sensitivity for ischaemic changes, and can detect haemorrhage using gradient echo sequences. Because

it takes longer than CT imaging and because there are more contraindications to its use, it may not be so useful in the emergency room. Diffusion-weighted imaging (DWI) is an MRI sequence that measures the degree to which water molecules are free to diffuse. Cells dying from ischaemia develop intracellular oedema as sodium ions enter the cell; water is thus removed from the extracellular compartment, resulting in reduced free diffusion of water. The consequent reduction in the apparent diffusion coefficient is detected as a signal on DWI. DWI therefore detects the extent of the core of the infarct. In perfusion-weighted imaging (PWI) a bolus of gadolinium is injected intravenously and its passage through the brain is then tracked, enabling areas of reduced perfusion to be identified, as measured for example by delays in the time-to-peak. What is of interest is the extent to which the area of reduced perfusion, identified on PWI, is larger than the core of dying tissue, identified on DWI. This area of DWI/PWI mismatch is thought to represent the penumbra. However, there may be situations when the DWI/PWI mismatch does not match the penumbra, for example because the DWI lesion includes some tissue that is in fact salvageable (Guadagno *et al.* 2004). Nevertheless, there are two clinical situations where DWI/PWI findings are useful. Patients with a middle cerebral artery stroke and a large extensive DWI lesion (i.e. the core) and little mismatch are very likely to do badly. The stroke may become 'malignant', with severe raised intracranial pressure and cerebral herniation; decompressive hemicraniectomy, to relieve the raised intracranial pressure, may reduce mortality in these patients. On the other hand, even as late as 3–6 hours after stroke onset, if there is a large area of mismatch (suggesting a large penumbra), then thrombolysis may improve outcome.

Any advantage in identifying DWI/PWI mismatch is largely limited to anterior circulation strokes. On the other hand, routine MRI combined with DWI is particularly useful for detecting posterior fossa or lacuna strokes. MRI gradient echo sequences can visualise intracerebral haemorrhages including microbleeds or petechial haemorrhages below the 5-mm-diameter threshold necessary for detection using CT. There is uncertainty as to whether such microbleeds should be regarded as a contraindication to thrombolysis. MRI can also identify occluded arteries, which lose the normal flow void within the lumen, or those with dissection of the wall. These observations may be complemented by visualisation of the occluded arterial tree by magnetic resonance angiography (MRA). MRI plus MRA is the method of choice for the diagnosis and follow-up of cerebral venous thrombosis as a cause of stroke (Masdeu *et al.* 2006). Other neuroimaging techniques that may have a role in the investigation of stroke include cerebral angiography and Doppler studies of the cerebral vessels.

Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) may demonstrate remote effects

(*diaschisis*) at a distance from the point of infarction (Baron 1987; Costa & Ell 1991). This is best observed in ipsilateral cortex, particularly frontal, after thalamic infarcts, in contralateral cerebellum after large supratentorial infarcts (crossed cerebellar diaschisis) (Sobesky *et al.* 2005), and in contralateral areas of cortex after unilateral cerebral ischaemia (transhemispheric diaschisis). The diaschisis may be accompanied by neuropsychological (Caselli *et al.* 1991) or neurological (Seitz *et al.* 1999) deficits that may recover quickly.

In the hours and days after stroke, neurological recovery is due to reperfusion. With improvement in blood flow the penumbra shrinks as neurones that were previously unable to function return to activity. This may be followed by a period of improvement over several weeks due to the spontaneous regression of brain oedema and other acute histopathological processes in and around the stroke. Over this same period the remote effects of the stroke, particularly diaschisis, improve. Any later recovery is probably, at least in part, due to reorganisation of function (Butefisch *et al.* 2006).

Frackowiak and colleagues used PET to investigate patterns of adaptation and reorganisation in patients who had recovered from hemiplegic stroke (Chollet *et al.* 1991). Finger movements on the unaffected side activated regional blood flow in the contralateral sensorimotor and premotor cortex and the ipsilateral cerebellar hemisphere. The same movements in the recovered hand produced more widespread activations, including significant increases bilaterally in sensorimotor and premotor cortex and both cerebellar hemispheres. Thus bilateral involvement of motor systems was seen when the recovered fingers were employed, indicating significant reorganisation and recruitment of ipsilateral motor pathways. In a further study, Weiller *et al.* (1992) obtained evidence of the recruitment of additional motor systems involving inferior parietal and anterior insular regions. Activations were also observed in cingulate and prefrontal areas that are not normally involved in finger movement but are known to be involved in selective attentional and intentional mechanisms, suggesting that these too may play an important part in the recovery process. Rather similar patterns of reorganisation, with activation of motor and premotor cortex contralateral to the lesioned side, have been identified using functional (f)MRI to study a finger-tracking task in patients several years after stroke (Carey *et al.* 2002). This reorganisation was only seen in those who were exposed to a motor training programme, compared with those who were not, an observation that has important implications for stroke rehabilitation.

Investigation and medical management of TIA and stroke

The management of stroke within 3 hours of onset is dominated by the need to determine whether there is any evidence of cerebral haemorrhage on neuroimaging. If there is no

haemorrhage, it may be possible to start thrombolytic treatment with recombinant tissue plasminogen activator (rt-PA). The sooner rt-PA is started, the greater the benefit. It will also be necessary to evaluate the patient's cardiovascular status; possible sources of emboli must be sought with care. Anti-coagulant therapy may be indicated where embolism is suspected, or operative intervention may be needed on a stenosed or atheromatous carotid artery, but these are matters for neurological assessment. More recently it has been proposed that in some cases with a large lesion on DWI in the middle cerebral artery territory early decompressive hemicraniectomy may reduce mortality. There is no evidence that neuroprotection helps.

Patients with intracerebral haemorrhage are at risk of further bleeding and of developing hydrocephalus. In the acute stage, expert nursing and physiotherapy are essential. Patients admitted to a stroke unit are less likely to die than those admitted to routine medical admission wards (Stroke Unit Trialists' Collaboration 2001). Particularly in the younger patient or those with recurrent stroke, specific causes of stroke should be considered (Box 8.4).

Sequelae of stroke

The disablement resulting from strokes is frequently a mixture of physical and mental problems. The latter may be attributable directly to the brain damage sustained, or largely represent the individual's reaction to the handicaps imposed on him. In either event the patient's personality and life situation can have a profound effect on overall adjustment to the disability, and the mental components of the picture will often be decisive in determining the level of success achieved in rehabilitation.

In what follows an attempt is made to review the principal components of psychiatric disability after stroke, but first the

question of overall prognosis is considered. The general picture of the incidence of defects and quality of survival provides the framework against which to view the range and extent of the problems encountered.

Overall prognosis

On average, after a stroke about one-quarter of patients die within 1 month (Wolfe 2000). The wide variation in mortality rates across studies, from 18 to over 50%, presumably reflects the differing age and health status of the populations studied. The highest mortality is associated with primary intracerebral haemorrhage and subarachnoid haemorrhage; 1-year case fatality is about 34–40%. In terms of impairment it has been estimated that at 6 months after the stroke (Wolfe 2000) about half continue to have partial or complete motor loss, one-quarter are not orientated and about 15% have a significant aphasia. As a result more than 20% of patients are at least moderately dependent. A population-based survey 5 years after stroke (Wilkinson *et al.* 1997) found one-third to be moderately or severely disabled, and two-fifths were more disabled than they had been at 3 months after the stroke. Presumably intervening vascular events and other effects of ageing explained some of the deterioration. Perhaps the high rates of depression also contributed to the deterioration; almost one-quarter were depressed. In a study of 286 survivors of stroke at 3 and 15 months (Pohjasvaara *et al.* 2002), both deteriorating depression and deteriorating cognition were associated with an increase in dependence at 15 months.

Early epileptic seizures, within the first week, are seen in about 3–6% of patients after ischaemic stroke (Camilo & Goldstein 2004; Ryvlin *et al.* 2006), but the risk is perhaps fourfold greater with intracerebral haemorrhage (Vespa *et al.* 2003). Other risk factors include a cortical lesion and severe stroke. Although only about 2–4% of patients will develop epilepsy in the longer term, stroke is the commonest single cause of late-onset epilepsy (Ryvlin *et al.* 2006). Those stroke patients who develop epilepsy probably have a worse outcome and may have greater risk of psychosis (see below). Early epileptic seizures may be a risk factor for cognitive impairment after stroke (Cordonnier *et al.* 2007).

Cognitive impairment and dementia

The mental impairment that may follow a single stroke usually proves to be focal in nature once the initial clouding of consciousness has cleared. For some time, however, global confusion and disorientation may be much in evidence, and can be slow to clear when cerebral damage has been extensive. It may be aggravated by anoxia from congestive cardiac failure or respiratory infection, or be attributable in part to the patient's difficulty in coping with new-found barriers to communication with his environment. As the situation improves the true extent of cognitive dysfunction is revealed. The longer clouding of consciousness has persisted, the

more likely that residual mental deficits are severe and extensive.

Considerable difficulty may be encountered in assessing the extent of global intellectual impairment, particularly if the patient is dysphasic or with marked constructional difficulties. Agitation, depression or apathy in the early stages may give a false impression of dementia, as may visual disorientation or agnosic difficulties. A circumscribed amnesic syndrome due to posterior cerebral infarction may not at first be appreciated as such.

Much of our understanding of the classic focal cortical syndromes (the dysphasias, apraxias and body image disturbances) has come from studies of stroke survivors. The essentials of such disorders have been outlined in Chapter 1 and are not repeated here. Such disorders have important impacts on rehabilitation. Disturbances of language contribute a large added handicap and source of frustration, frequently outlasting recovery of motor function. Patients with expressive loss but good comprehension will in general make much better adjustment than when understanding is faulty. Apraxic disturbances may persist as a barrier to rehabilitation when motor paralysis has cleared, particularly an apraxia of gait. Disorders of attention, including neglect, often improve spontaneously but otherwise may prove difficult to treat particularly as they are often accompanied by lack of insight.

The concepts of vascular dementia and multi-infarct dementia are discussed alongside the other dementias in Chapter 9. The focus here is on *poststroke dementia*, a term introduced to describe those patients found to suffer global cognitive impairment after stroke (Leys *et al.* 2005). Thus the index event in studies of poststroke dementia is the stroke, and all types of dementia irrespective of their cause are included. The most common are vascular dementia and Alzheimer's disease. In some cases the dementia will have been present before the stroke, in others the stroke will have caused the dementia, and in others the dementia will have had its onset at some time between the stroke and the assessment.

Estimates of the prevalence of poststroke dementia vary widely, from 6 to 32%. Much of this variance may be because of the different classification criteria that have been used. The age of the cohort studied and the interval between assessment and stroke will affect prevalence rates. Stroke doubles the risk of new-onset cases of dementia (i.e. not present when assessed shortly after the stroke) over the years after the stroke (Kokmen *et al.* 1996), and this includes a doubling of the risk of Alzheimer's disease. Risk factors for poststroke dementia include lower educational level, prestroke cognitive decline (but not sufficient for dementia diagnosis), and more severe stroke. Left hemisphere strokes are more likely to be associated with dementia. Dementia after stroke is more common in those who, on CT or MRI, have silent infarcts (i.e. infarcts not associated with any corresponding neurological

defect), global atrophy or white matter disease (leucoaraiosis) (Leys *et al.* 2005).

Very occasionally dementia may follow a single strategically situated stroke. The syndrome of cognitive impairment after strokes of the left angular gyrus, with a receptive aphasia and constructional deficits, may easily be mistaken for the clinical picture found in Alzheimer's disease (Benson & Cummings 1982). Bilateral strokes involving the basal forebrain can produce a dementia as a result of severe impairment of executive function and memory. Bilateral thalamic strokes may produce dementia. De Boucaud *et al.* (1968) reported an example with post-mortem findings of old haemorrhagic softenings in both thalami and no pathological changes in the cortex. The dementia was accompanied by disturbance of gait. Bilateral medial thalamic infarctions typically lead to a hypersomnolent apathetic state and vertical gaze disturbance, with dementia of the 'subcortical' type (Kumral *et al.* 2001). Such lesions are seen with occlusion of the paramedian arteries of the thalamus. Indeed because the thalamus is supplied by four arteries, each with a very distinct origin and territory, thalamic strokes may be quite localised and offer unique insights into brain-behaviour relationships. It has been suggested that distinct patterns of behavioural change, even following unilateral lesions, can be seen depending on which of the four main thalamic arterial territories is affected (Carrera & Bogousslavsky 2006). Infarcts of the anterior thalamic territory may produce apathy, amnesia and a behavioural syndrome (still to be validated by other research groups and which perhaps bears some semblance to confabulation) of perseveration and 'superimposition of unrelated information'; amnesia, loss of self-activation and disinhibition with personality change follow paramedian infarcts; executive dysfunction follows inferolateral lesions, and neglect and aphasia after posterior lesions.

Poststroke dementia has a serious adverse effect on both the mortality (Desmond *et al.* 2002) and morbidity of stroke. It also increases the risk of stroke recurrence. Deficits in cognitive function are therefore among the more serious of the sequelae of stroke, delaying and often gravely compromising attempts at rehabilitation. Such elements in the clinical picture may be less immediately obvious than the hemiplegia or other physical handicap, yet often prove to be the factors responsible for failure to regain independence. Thus among patients who become long-stay invalids, permanently confined to chair or bed, paralysis by itself rather seldom accounts for their incapacity and may even contribute little towards it (Adams & Hurwitz 1963, 1974).

Personality change

Personality changes after stroke are among the most troublesome of the sequelae of stroke, and may overshadow the intellectual deficits. It may be difficult to determine if the change in personality is directly attributable to brain damage. When this is the case, widespread vascular changes are probably responsible and the personality change may progress even though the focal sequelae of the stroke improve. The changes usually prove to be the prelude to a progressive dementing illness.

A woman of 69 had a very mild stroke affecting the left arm transiently. She seemed well for a while thereafter, but gradually changed, becoming irritable, hard to please and with vague complaints of headache and giddiness. She became anxious and did not want to be left alone. Loss of interests and slowing were accompanied by episodes of confusion and disorientation. On examination 15 months after the stroke she was not grossly demented, but showed some difficulty in understanding questions and had only a vague idea of the date. There was a residual left hemiparesis, a left homonymous hemianopia, some dyscalculia and a mild nominal dysphasia. However, her affective state was worse than her intellect: she was mostly apathetic and dull, though cheerful in a facile way at times. Eventually she needed long-term hospitalisation (Slater 1962).

In such cases the pattern of problems encountered is not dissimilar to those found in any dementing illness. Typically one sees a 'reduction of margins'. The patient cannot adjust to new circumstances, and small matters make him anxious, irritable or depressed. He avoids new experiences and restricts himself to an unvarying routine. Confrontation with a task or with social demands carries the risk of provoking a catastrophic reaction. The patient may become abusive and uncooperative if asked to make any effort, yet be affable and obliging when left in peace. Hypochondriacal concerns may become evident and constitutional predispositions may also be revealed or accentuated. A previously lonely person may become suspicious or frankly paranoid. It may be only at a later stage, when for example the emotional state is recognisably abnormal with dulled and flattened responsiveness, that it becomes evident that the patient has a dementia.

When the carers of unselected cohorts of patients with stroke are asked to describe the personality changes, several attributes are typically endorsed. At 1 year after stroke over half of 84 patients were rated by their carers as being slowed down, excessively worried, miserable or complaining of aches and pains, and over one-third as withdrawn, irritable, fearful or unpredictable (Anderson *et al.* 1995). At 9 months after the stroke, patients were rated as being more bored, frustrated, unhappy, worried, irritable and unreasonable, and less active, independent, patient, confident and enthusiastic compared with the retrospective assessment of the pre-stroke state (Stone *et al.* 2004). Greater changes in personality were reported in patients who were diagnosed as depressed, who had worse scores on an extended activities of daily living scale, and for whom the carer had more emotional distress as rated by the carer's score on the Hospital Anxiety and Depression Scale (HADS). Patients with total anterior circulation strokes were most at risk.

Caregiver burden

Much of the burden of care of stroke comes to fall on carers, often the spouse of the patient and themselves no longer young. Early in the course of adopting this responsibility carers will express their concerns about the challenge. When this was examined during rehabilitation on average 12 weeks after injury (Belciug 2006), carers were worried about making sure that the patient would be safe at all times and dealing with the emotional aspects of the patient's care. Carers also wanted to know what the future needs would be and what to do in specific situations when the patient could not do something for himself. These anticipatory worries may partly explain why carers rate the patient as more impaired than patients rate themselves (Knapp & Hewison 1999). However, at 3 years carers remain burdened by feelings of heavy responsibility, uncertainty about patients' care needs, constant worries, restraints in social life, and feelings that patients rely on them alone (Scholte op Reimer *et al.* 1998).

A review of 20 studies of caregivers of stroke patients found that about 40% of carers are depressed (Han & Haley 1999). When non-caregiver controls had been studied they showed much lower rates of depression. How much of the effect is specific to looking after patients with stroke, as opposed to other disabled patients, is uncertain. Carers with worse social networks and worse physical health report more depressive symptoms. The carers of patients who were depressed or had more abnormal behaviour were also more likely to be depressed. Nevertheless, carers of patients who were more physically dependent did not seem to be at increased risk. Some studies suggest that carer ill health may deteriorate over time after the injury (Scholte *et al.* 2006). However, one 2-year follow-up found relatively low levels of carer stress and depression, and these remained fairly constant over time (Wade *et al.* 1986). Associations between patient characteristics and carer depression, including being less independent or more depressed, present in the first year after stroke were no longer present at 2 years.

Does stress in the caregiver result in worse outcome for the patient? The best test of this is to demonstrate that interventions, directed at the carer to reduce carer burden, improve patient outcome. As yet there is little evidence to support this. Indeed it may not be easy to relieve caregiver burden. A review of studies designed to improve well-being in carers using problem-solving interventions found some effects in some studies (Lui *et al.* 2005). For example, in a randomised study of patients and their families a few weeks after stroke, one-third of caregivers were visited at home to be taught problem-solving skills using a systematic four-step approach (Grant *et al.* 2002). Telephone contact, initially weekly, was then used to consolidate the intervention. After 3 months the intervention group, compared with a sham intervention and a control treatment-as-usual group, showed better problem-solving and were less depressed. However, they did not

show less carer burden. The study did not attempt to examine any impact the intervention might have had on the patients themselves. In a study of 240 stroke patients randomised to receive visits from a specialist outreach nurse to provide information, advice and support over the first 12 months compared with treatment as usual, there was no reduction in stress in carers (Forster & Young 1996). Mildly disabled patients showed small gains in activity. In a randomised controlled trial (RCT) of a family support organiser, aimed at both patient and carer, those who received the intervention did obtain more social services support and felt better informed, but there was no significant improvement in a measure of reintegration into normal living (Tilling *et al.* 2005). Therefore it is not yet possible to give firm advice as to what technique to use to reduce carer stress, and whether in fact it will make much difference anyway.

Depression and other mood disorders

It is scarcely surprising that depressive reactions should be common in survivors of strokes. Ullman (1962) vividly describes the subjective impact which the experience may have. The patient finds himself abruptly in the grip of something novel, frightening and ill understood. Even slight interference in free communication with those around will greatly intensify feelings of isolation, threat or loss. When the acute stage is over there is a variety of factors around which depression may come to be organised: the frustrations of physical handicaps, uncertainty about the prospects of their resolution, the enforced dependency and imposition of the invalid role. In the longer term the patient may face loss of job and status, financial insecurity, a sense of uselessness or the prospect of permanent loss of independence.

At what stage should such depressive reactions be regarded as a case of depression? It could be argued that there is a danger of overestimating depression after stroke if physical symptoms of stroke are interpreted as evidence of depression (Box 8.5). Patients diagnosed with depression after stroke, compared with primary depression (depression that is not secondary to brain disease or other factors), have more physical symptoms and less evidence of melancholia (Beblo & Driessen 2002). However, somatic symptoms are not necessarily a confounder. Depressed stroke patients are much more likely to endorse symptoms like fatigue and sleep disturbance than stroke patients who are not depressed (Williams *et al.* 2005). Nevertheless, depression in patients who are aphasic after stroke may be missed.

Most studies find that survivors of stroke, when compared with age-matched controls, are more depressed. Indeed stroke patients have been found to show a higher incidence of depression than orthopaedic controls or patients suffering from traumatic brain injuries, despite equivalent levels of disability in terms of activities of daily living or cognitive dysfunction (Folstein *et al.* 1977; Robinson & Szetela 1981). However, one study comparing survivors of stroke with

Box 8.5 Depression in stroke (Royal College of Physicians 2005)

Reasons why depression may occur after stroke

- An emotional response to the sudden onset of disability and its associated changes
- Direct result of the brain injury, leading to altered biochemical balance within the brain producing changes in mood
- Preceding tendency to depression or history of depression

Reasons why symptoms that may mimic depression may occur after stroke

- Other emotional disorders associated with stroke, such as apathy or emotional lability, may give the appearance of depression
- Somatic symptoms that characterise depression in the normal population may occur as a result of hospitalization or from the stroke itself. These symptoms may include loss of energy, appetite and libido; altered sleeping pattern; and poor concentration or inability to make decisions
- Abnormal appearance of the emotional status may give the appearance of depression, e.g. disorders of facial expression, flat speech patterns, general physical slowness

survivors of myocardial infarction found no difference (Aben *et al.* 2003).

A systematic review of studies of depression after stroke found that the estimates of the prevalence of depression vary according to which rating scales have been used (Hackett & Anderson 2005), but that even using clinical assessments, e.g. based on *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-IV criteria, there is considerable variation in reported frequencies across individual studies. Nevertheless, when the findings across studies were collated the pooled estimates were fairly consistent, indicating that about one-third of patients had significant depressive symptoms, regardless of whether the cases were ascertained from the community, from hospital or from rehabilitation settings. The pooled estimates of the time course of depression were largely based on different cross-sectional studies, each study assessing depression at a different time after stroke; only a small minority of studies had longitudinally assessed depression. Whether the study was early, in the first few weeks and months after stroke, or late, on average the rate of depression did not change. However, even though the rate of depression at each time point remains fairly constant, depression early after stroke has a good chance of remitting over the course of the first year; this is counterbalanced by the finding that other patients become depressed for the first time many months after stroke. Nevertheless, some longitudinal studies show a trend for rates of depression to decline over the first

1–2 years (Morris *et al.* 1990; House *et al.* 1991; Astrom *et al.* 1993; Verdelho *et al.* 2004), but not all studies (Wade *et al.* 1987; Herrmann *et al.* 1998).

Based on the same systematic review of papers, Hackett and Anderson (2005) found that the best predictor of depression was stroke severity, including the extent of physical disability and cognitive impairment. One matter of interest is whether the laterality of the stroke is related to depression. Early studies suggested that left hemisphere infarcts, particularly if located anteriorly, were more likely to produce depression (Robinson & Price 1982; Robinson *et al.* 1984), although a systematic review of studies reporting rates of depression related to laterality of stroke found no effect (Carson *et al.* 2000). However, this conclusion has been rebutted (Narushima *et al.* 2003) and one systematic review (Bhogal *et al.* 2004) found that left-sided stroke is associated with depression if the study examines patients early after stroke, or in hospital. More recent studies have failed to demonstrate an effect of laterality (Verdelho *et al.* 2004; Nys *et al.* 2005; Aben *et al.* 2006; Paolucci *et al.* 2006).

It seems likely that biological factors will be especially important in the early weeks following the infarct (Nys *et al.* 2005), but that with the passage of time, social and interpersonal factors will become increasingly important in determining the affective state. Clinical wisdom suggests that depression will be strongly determined by aspects of the pre-morbid personality. Patients of striving and self-sufficient disposition may react more adversely to handicap and those who have experienced anxiety and depressive reactions under previous stress will be at increased risk. Neuroticism, as assessed by self-rating 1 month after stroke on the NEO Five Factor Inventory (Costa & McCrae 1985), has been found to be associated with depression (Aben *et al.* 2006). Much will also depend on the family setting and relationships with which the patient is surrounded. Quite frequently, at the era of life where most strokes occur, the patient is relatively unsupported: the spouse may have died or be infirm, and children will have moved away. In their systematic review Hackett and Anderson (2005) found that adverse social factors, particularly those related to social isolation, are associated with depression. However, it was less easy to demonstrate, consistently across studies, effects of age, personal history of depression or stroke subtype. Possible reasons for the discrepancies among the different investigations are likely to include differing levels of physical and cognitive impairment, pre-existing brain damage as well as the time elapsed since the stroke occurred. A host of psychosocial variables in the samples studied may be important, including the proportion of patients having religious beliefs, which may protect against the development of depression (Giaquinto *et al.* 2007).

On occasion it may be difficult to recognise depression, especially when the development has been insidious. Sometimes it is masked by stoical attitudes, or absorbed into

habitual or automatic patterns of behaviour. The importance of recognising depression need scarcely be stressed. Stroke is associated with suicidal thoughts in perhaps 10% of patients (Kishi *et al.* 1996; Pohjasvaara *et al.* 2001; Williams 2005) and probably doubles the risk of suicide (Stenager *et al.* 1998; Teasdale & Engberg 2001). Depression may lead to lack of cooperation or poor motivation for rehabilitation, and is associated with generally worse outcomes (Williams 2005) and greater use of health care (Jia *et al.* 2006). It is associated with greater depression in carers (Dennis *et al.* 1998). Depression early after stroke increases mortality over the subsequent years (Morris *et al.* 1993; House *et al.* 2001; Williams *et al.* 2004). Indeed depression probably increases the risk of having a stroke in the first place (Williams 2005).

Emotionalism after stroke

A heightened tendency to cry, often uncontrollably and with little warning, has traditionally been attributed to pseudobulbar palsy resulting from bilateral lesions of the corticobulbar tracts. In such a setting, crying may occur with little or no provocation. However, the disorder has broader connotations, and is not uncommon as an embarrassing and disabling aftermath of strokes.

House *et al.* (1989) followed up 128 patients who had suffered a first-ever stroke and examined them specifically for heightened emotionalism. The criteria were that the patient should experience an increase in episodes of crying (or more rarely laughing), with little or no warning, and with an inability to control them. At 6 months, 21% of patients reported such symptoms, and at 12 months 11%. All showed crying as the principal problem, but two had episodes of pathological laughter in addition. In most the disorder had set in during the 4–6 weeks following the stroke, with a tendency to ameliorate over the following year. In virtually all patients the episodes were provoked by emotional stimuli of a sad or sentimental nature.

The patients as a group scored higher on indices of depression than the remainder, but they were also more intellectually impaired and showed more extensive lesions on CT. A special relationship appeared to obtain with lesions in the anterior left hemisphere, patients with such lesions showing longer-lasting disorder. Stroke survivors with emotionalism, compared to those without, exhibit more irritability and ideas of reference (Calvert *et al.* 1998) and intrusive thoughts about their stroke (Eccles *et al.* 1999).

Prevention and treatment of poststroke depression and emotionalism

Though it is hoped that appropriate treatment can be quickly rewarding, it is important to distinguish depressive disorder from simple loss of confidence, or from the emotional lability associated with intellectual impairment. It is also necessary to remain sensitively aware that sometimes,

in severely disabled patients, feelings of resignation and futility are realistically based; some elderly patients really are so frail, and the odds so genuinely against them, that their wish 'not to bother' deserves to be treated with proper respect. Needless to say this is an aspect of differential diagnosis that requires the utmost care.

Given that probably one-third to half of patients go on to suffer depression in the year after stroke, and that depression is associated with adverse sequelae (see above), several studies have attempted to prevent depression after stroke. Most have used antidepressants prescribed prophylactically to all patients, whether depressed or not, to see if patients on drug treatment are less likely to become depressed over subsequent months. For example, 137 patients were randomised to receive sertraline or placebo within 4 weeks of stroke (Rasmussen *et al.* 2003). Significantly fewer scored above cut-off on the Hamilton Depression Rating Scale at 1 year, although this finding was jeopardised by the fact that half had dropped out of the study by then. In fact a rigorous systematic review (most recently updated in August 2005) concluded that there was insufficient evidence to support the clinical argument that antidepressants should be used to prevent depression after stroke (Hackett *et al.* 2005). In only five of nine studies was it possible to estimate whether rates of diagnosable depression were reduced. There was a significant finding in favour of antidepressants, but this relied heavily on one study that used indoloxine, a drug not generally available, as well as the study using sertraline just described. Nevertheless, no adverse effects were found related to antidepressant use. The review concluded that if it were possible to identify patients at high risk of depression, there might be a role for prophylactic antidepressants for these patients. A more recent review found in favour of antidepressants for preventing depression, although the review included studies with only 4-week treatment trials (Chen *et al.* 2006). There have been two more recent studies with reasonable durations of treatment, in both cases started within 2 weeks of stroke. Almeida *et al.* (2006) compared 24 weeks of sertraline with placebo; there was no significant reduction in rates of depression in patients on sertraline. The other study by Niedermaier *et al.* (2004) compared 1 year of mirtazapine with treatment as usual (no placebo so the study was not blinded); fewer on mirtazapine suffered depression. Given these ambivalent findings, at present the evidence probably does not justify the routine use of antidepressants in all patients who have suffered a stroke.

The review by Hackett *et al.* (2004) also found three studies of psychotherapeutic techniques aimed at preventing depression. Using the General Health Questionnaire (GHQ) as a measure of psychological distress, there was a small effect in favour of psychotherapy (weighted mean difference -1.41; CI -2.64 to -0.18). However, this result relied

heavily on the positive results of one study and there was no significant effect on reducing rates of depression. More recently, a study of a 3-month exercise programme after stroke, designed to investigate general improvements in outcome, found that at 3 months significantly fewer of the exercise group were depressed (14% vs. 35%), although by 9 months the effect was no longer statistically significant (Lai *et al.* 2006).

Turning now to the effectiveness of antidepressants in relieving poststroke depression, several studies have been published since this was first documented by Lipsey *et al.* (1984). On the basis of a systematic review of these studies, Hackett *et al.* (2004) concluded that there was no strong evidence that antidepressants were able to increase rates of remission of depression after stroke. However, there was evidence of a reduction (improvement) in scores on depression rating scales. Even though the findings of the review have been disputed (Chen *et al.* 2006), it seems reasonable to conclude that while antidepressants do improve mood in patients who are depressed after stroke, the effect is not as great as in primary depression, i.e. in patients without brain disease. Given that antidepressants may increase anxiety when used to treat poststroke depression (Hackett *et al.* 2004), some would argue that they should only be used if there is good evidence of major depression. On the other hand, because selective serotonin reuptake inhibitors (SSRIs) are unlikely to produce side effects, perhaps all patients with possible depression (e.g. those with poor motivation) should be treated; not to do so may mean that patients who might benefit are not given the opportunity. However, any such therapeutic trial needs to be closely monitored for evidence of benefit, and if none is found there should be a clear protocol for stopping the antidepressant.

In the absence of powerful effects of antidepressant medication, it is all the more important to consider psychological treatments of poststroke depression. These were evaluated in an RCT of patients with depression 1–6 months after stroke (Lincoln & Flannaghan 2003). They were offered 10 sessions of cognitive–behaviour therapy, delivered by a community psychiatric nurse, over 3 months or an equivalent level of contact but with no formal cognitive–behaviour therapy (attentional placebo) or treatment as usual; there were about 40 patients in each arm. There was no effect on depression. On the other hand, a study of care management of depression, with patients recruited 1–2 months after stroke, found lower rates of depression after 12 weeks in the treatment group compared with treatment as usual (Williams *et al.* 2007). However, the care management intervention ('Activate–Initiate–Monitor') was essentially aimed at improving compliance with antidepressant medication. Therefore far higher rates of antidepressant use were seen in the treatment group. As such it is difficult to be sure how much of the effect

was due to any psychological support the patients received, and how much was due to antidepressants. Nevertheless, the findings support clinical wisdom; if antidepressants are going to be prescribed this is best done in the setting of a clear management plan (see for example the guidance for prescribing antidepressants following acquired brain injury; Royal College of Physicians 2005).

Given such ambivalent findings in terms of the treatment effects of antidepressants, it is too early to be convinced by suggestions that antidepressants may improve cognition or reduce mortality after stroke. However, tricyclic antidepressants have also been shown to be remarkably effective in patients who develop 'emotional incontinence' with pathological laughing and crying, whether or not this is associated with other features of pseudobulbar palsy (Lawson & MacLeod 1969). Even in the absence of subjective depression, such medication can apparently alleviate the disruptive and socially embarrassing effects of the disorder. A systematic review of the evidence was less optimistic. It concluded that large effect sizes could be seen, but noted that the confidence intervals were wide and that there was no consistency across studies in terms of the measure of emotionalism or the antidepressant that had been used (House *et al.* 2004). Despite these cautions most clinicians would recommend a trial of an SSRI in somebody with disabling emotionalism after stroke.

Other mood disorders

A generalised anxiety disorder is found in about 25% of stroke patients (Castillo *et al.* 1995; Leppavuori *et al.* 2003) usually in association with depression. In a careful follow-up of patients, House *et al.* (1991) stressed the importance of persistent agoraphobia and social withdrawal in a small proportion of cases. Such developments were often associated with fear of looking conspicuous on account of disabilities, or fear of recurrence provoked by physical activity. Tension, worry and lack of energy were common complaints.

Mania occurs after stroke, but not sufficiently frequently to reliably estimate its prevalence. Mania may be associated with right temporal lesions (Starkstein *et al.* 1990). Hypomanic pictures have also been reported (Van der Lugt & De Visser 1967), and from the data presented by Starkstein *et al.* (1988) may be expected to be commoner after right hemisphere strokes than left. They reported 12 cases of mania after a variety of brain lesions, seven being restricted to the right hemisphere, one to the left, and four with bilateral or midline damage. Of the four strokes in this series, two were in the right hemisphere, one in the left and one was a right thalamo-capsular bleed. The episodes of mania often followed the strokes within days or weeks.

A remarkable example of bipolar affective disorder following thalamic infarction was described by McGilchrist *et al.* (1993).

A 43-year-old man with mild hypercholesterolaemia and indications of autoimmune dysfunction experienced an episode of transient loss of consciousness, followed by drowsiness and left-sided pyramidal signs for 24 hours. Thereafter he appeared to have undergone a marked change of personality, becoming apathetic, dulled and fatuous, and eating and sleeping excessively. At intervals of 3 weeks or so he would suddenly become alert, excitable and elated for about 36 hours, then relapse to his former condition. The picture was sufficiently bizarre to suggest at one time that he might be malingering.

When referred for a second opinion 18 months later he was histrionic and tearful, smiled incongruously and had poor self-esteem. He was profoundly apathetic and self-care was poor. He complained that he was like 'an engine that won't tick over'. CT revealed bilateral thalamic infarcts, and SPECT showed severe hypoperfusion of both frontal lobes. Psychological testing showed poor performance on a visual memory task and impaired frontal functioning on the Trail Making and the Cognitive Estimates tests. While in hospital he showed two episodes of elation lasting for several days, the second being frankly manic with pressure of speech, flight of ideas and possibly auditory hallucinations.

It was concluded that the thalamic infarctions had led, via diaschisis, to metabolic hypofunction in the frontal lobes, resulting in the abrupt onset of cyclical mood disorder accompanied by features of frontal lobe dysfunction.

Attention has been drawn to another aspect of differential diagnosis by Förstl and Sahakian (1991). Three patients were described who were admitted to hospital with supposed major depression, exhibiting severe psychomotor retardation, weight loss, exhaustion and self-reproach. All had evidence of infarcts or atrophy in the left frontal lobe, and SPECT scanning in two showed left frontal hypoperfusion. The shared clinical feature was abrupt improvement under hospital care, with relapse to extreme lack of initiative and energy on discharge to the home environment. Such cycles were followed repeatedly, with the patients neglecting to eat or drink and spending most of their time at home in bed. It was suggested that this may represent a specific syndrome of extreme abulia (i.e. lack of will) consequent on left frontal pathology. Milder forms of apathy are quite common after stroke, and though they are usually observed in patients who are also depressed, may be seen in isolation (Starkstein *et al.* 1993).

Psychoses

There are few figures against which to gauge the incidence of non-affective psychotic illness after cerebrovascular accidents; it has been estimated at about 1–2% (Rabins *et al.* 1991), although follow-up series will fail to find any cases at 1 year (Tang *et al.* 2002). The most thorough study of the incidence of delusional ideas rated 360 patients admitted within 1 day

Fig. 8.2 Location of strokes in 15 patients with delusional ideation in the days following stroke. (From Kumral & Ozturk 2004 with permission.)

of stroke every day while they were in hospital (Kumral & Ozturk 2004). Delusional ideation was found in 15 patients (4%), with onset within a few days of stroke. It was often associated with other behavioural problems, for example agitation. All patients were treated with haloperidol or quetiapine and the delusions lasted on average 13 days, tending to ameliorate alongside the other behavioural problems. All patients with delusional ideas had right hemisphere stroke (Fig. 8.2), particularly posterior temporo-parietal, and they also tended to show mild evidence of generalised cerebral atrophy. It was therefore not surprising to find that in four cases there was Capgras delusion, and one other case of delusional misidentification. These findings are very much in line with Price and Mesulam (1985), who described five cases of delusions occurring in the acute phase after stroke, all with right hemisphere lesions.

Levine and Finklestein (1982) have also noted an apparent relationship between cerebrovascular lesions of the right hemisphere, specifically of the right temporoparieto-occipital areas, and the development of psychotic illnesses some time later. Eight patients were described, with the psychoses

appearing some weeks or years after the stroke. All but one had developed seizures in the interim, which may have been a connecting factor. The psychoses developed acutely, with formed auditory and visual hallucinations; the majority of patients showed agitation, persecutory delusions and confusion, but in some the hallucinatory phenomena were relatively pure. All had constructional apraxia, and most showed a variety of other neurological residua. The right-sided location in every case may have reflected the freedom from dysphasia, allowing the psychoses to be revealed, or alternatively may have reflected the predisposing effects of spatial disabilities in leading to environmental misinterpretations. The combination of right hemisphere infarcts with poststroke seizures as a risk for psychosis has been found in a further five cases (Rabins *et al.* 1991). Pre-existing subcortical atrophy appeared to be an additional risk factor.

Hallucinoses, in which the patient retains insight into the unreal nature of the hallucinated material, has traditionally been related to lesions in the midbrain and pons, the peduncular hallucinosis of Lhermitte (1922, 1932) described in Chapter 1 (Basic concepts and terminology/Organic hallucinosis). Such hallucinosis can occur in the visual or auditory modalities, is typically complex and vivid, and usually resolves within days or weeks. The midbrain lesion responsible has been demonstrated on MRI (Geller & Bellur 1987). On the other hand, hallucinations may be seen after cortical strokes; 4 of 641 patients had auditory hallucinations in the early poststroke period and in all cases the lesion was in the right temporal lobe (Lampl *et al.* 2005).

Given the concern that antipsychotics, when used to treat psychosis in the elderly, may be associated with an increased risk of stroke, care is required when prescribing these agents to patients who have suffered a stroke. Psychosis in the early days after stroke may well resolve spontaneously. If antipsychotics are to be prescribed, any potential risks should be discussed with the patient and the family.

Rehabilitation after stroke

The processes of recovery after stroke are largely spontaneous. Early recovery involves resolution of the histochemical effects of the stroke. As noted above, targeted treatments during this period are aimed at promoting survival of cells in the penumbra. However, numerous less specific matters need to be addressed that can all be considered under the rubric of rehabilitation. Good guidance on what should be available has been published (Bates *et al.* 2005) (Box 8.6).

Patients who receive organised inpatient care, as generally provided on a stroke unit, over the early days and weeks are more likely to be alive and independent at 1 year (Stroke Unit Trialists' Collaboration 2001). The care will optimise the systemic management of the patient, e.g. by paying close attention to hydration, blood pressure and assessment of swallowing function. Nursing and therapy will minimise

Box 8.6 Management of rehabilitation after stroke

(from Bates *et al.* 2005)

- The primary goal of rehabilitation is to prevent complications, minimise impairments and maximise function
- Secondary prevention is fundamental to preventing stroke recurrence
- Early assessment and intervention are critical to optimise rehabilitation
- Standardised evaluations and valid assessment tools are essential to the development of a comprehensive treatment plan
- Evidence-based interventions should be based on functional goals
- Every candidate for rehabilitation should have access to an experienced and coordinated rehabilitation team to ensure optimal outcome
- The patient and family and/or caregiver are essential members of the rehabilitation team
- Patient and family education improves the likelihood of informed decision-making, social adjustment and maintenance of rehabilitation gains
- The rehabilitation team should utilise community resources for community reintegration
- Ongoing medical management of risk factors and comorbidities is essential to ensure survival

secondary complications such as bed sores, contractures and subluxation of joints. As soon as feasible more specific rehabilitation will be available, early on relying heavily on physiotherapy (Young & Forster 2007). It is possible that such early rehabilitation interventions can influence neuroplastic change such that there is transfer of lost functions to unaffected brain areas, and reorganisation within the brain to allow other areas to contribute more. There is good evidence that physiotherapy is helpful, particularly in terms of exercise training to improve balance and gait. However, attempts to demonstrate the value of physiotherapy in improving limb function, as in hemiparetic stroke, have been less successful. Likewise there is little good evidence to demonstrate that speech and language therapy can improve dysphasia, though the speech and language therapist is likely to have an important role in assessment of swallowing function and helping to improve communication.

Later rehabilitation is likely to concentrate on adaptive responses and coping strategies. It may proceed in the hospital, the home or specialised rehabilitation units, depending on circumstances and the severity of the problems involved. Proper liaison among the different members of the team is essential for success, also adequate continuing care when the patient returns home. Therapy targeted at patients who have returned home can improve outcome, a review of the evidence suggesting that for every 100 patients treated, seven

will be spared a poor outcome (Outpatient Service Trialists 2003). Ongoing physiotherapy may be required but there is likely to be greater input from the occupational therapist who will concentrate on matters of fine motor control, particularly in the upper limbs. Retraining may be needed for activities of daily living: how to dress, feed, wash and cook despite the handicaps that persist. The provision of simple mechanical aids can be of immense help in restoring capabilities that would otherwise be lost. Community occupational therapy is effective at improving activities of daily living including mobility and use of public transport (Walker *et al.* 2004).

Sensory handicaps gravely complicate rehabilitation, particularly sensory impairments in paralysed limbs. Loss of position sense that persists after the early weeks carries a bad prognosis in hemiplegic patients, and may need special training under visual and tactile control. Cortical sensory loss, with defective discrimination, adds to difficulties with fine manipulation of the fingers. Hemianopic or quadrant field defects tend to resolve with time, or the alert patient learns to compensate for them. However, in the early stages or when there is mental impairment, care must be taken to approach the patient from the sound side, and to arrange the disposition of belongings and work materials accordingly. Refractive errors or defective hearing must not be overlooked as remediable sources of additional difficulty.

Rehabilitation for cognitive impairments has received much interest and more detailed guidance on what should be offered, based on evidence of efficacy, has been produced by a European Federation of Neurological Sciences Task Force (Cappa *et al.* 2005). Even though this was a review of therapy for all causes of acquired brain injury, including traumatic brain injury and stroke, the principles are nevertheless by and large relevant to stroke.

Disturbed body awareness and sensory inattention can provide a serious obstacle to progress. A tendency to ignore the left half of space may be a greater barrier, contributing to falls and mishaps and hindering mastery of a new environment. Persistent denial or disowning of hemiplegic limbs carries an especially poor prognosis for recovery of independence, and is often accompanied by prolonged incontinence. Unilateral neglect is more common with right hemisphere stroke. One study found 43% of right hemisphere stroke as opposed to 20% of left-sided stroke had neglect at the time of presentation, falling to 17% and 5% respectively at 3 months (Ringman *et al.* 2004). Most cases therefore resolve spontaneously within weeks and there is no good evidence that stimulation and exercises improve on this (Lincoln & Bowen 2006).

Communication disorders warrant close and early attention. The dysphasic patient has lost not only the ability to speak but also his primary means of relating with those around. Once communication is re-established, however small in degree, the patient's frustration and fear begin to diminish. A first aim must be to establish emotional contact with the

patient, using whatever channels of communication are most intact. Pictures may be used with which he can indicate requests, even though he cannot read or speak. Cards with words or short phrases may be useful later on. Gestures or visual signs may be employed when verbal understanding is very poor, coupled with one or two concrete words but avoiding a confusing flow of speech. Later in recovery instructions must be carefully spaced, given slowly, and as far as possible in the same manner on each occasion. Thus a special approach is needed from all the staff. Every attempt must be made to avoid withdrawal after early failures, to keep the patient involved and active, and to stimulate a continuing desire to communicate.

Formal speech therapy has rarely been rigorously tested, which is surprising in view of the magnitude of the problem. A Cochrane systematic review of the evidence concluded that 'speech and language therapy treatment for people with aphasia after a stroke has not been shown either to be clearly effective or clearly ineffective within a RCT' (Greener *et al.* 2000). Nevertheless, although it is uncertain whether the final level achieved exceeds that which would have occurred spontaneously, few doubt the effects of retraining programmes on emotional adjustment and morale.

Impairment of memory must be specially catered for with a more gradual programme, frequent rehearsals and the provision of props and supports by way of notes and written instructions. The relative preservation of old memories may initially produce a misleading impression until ability to acquire new knowledge is specifically tested. Strategies for rehabilitation of memory impairments rest largely on the premise that it will not be possible to affect the degree of impairment, but that by using compensatory strategies it may be possible to reduce the consequent disability and handicap that the memory impairment produces. More general techniques concentrate on organising the study of material to be learned, chunking information into subsets and breaking down new skills into a series of steps. More specific methods include the use of mnemonic devices such as first-letter cueing, rhyming strategies, visual imagery, or 'motor coding' whereby a movement is associated with a name to be remembered. Where multiple items are to be remembered these may be 'pegged' to a standard list of words, or to standard loci such as body parts or rooms within a house. Embedding the items in a brief manufactured story can be particularly effective. A review of memory rehabilitation across patients with different acquired brain injuries, including stroke, found errorless learning to be effective, whereas the case for the method of vanishing cues was not so robust (Kessels & de Haan 2003). However, there have been rather few attempts to demonstrate in stroke patients alone that rehabilitation can improve memory (Majid *et al.* 2000).

Other intellectual impairments are a serious barrier to progress when at all extensive. Ill-sustained attention, perseveration, fatigability and failure to grasp instructions may

combine to render attempts at rehabilitation fruitless. To maximise the chances of success, verbal instructions must be presented in simple language with deliberate methodical repetition. Practical demonstrations of what is expected may get the ideas across when other methods have failed. The pace will necessarily be slow, and allowance must be made for variability in performance from day to day.

Motivation is among the most crucial determinants of progress and every means must be taken to optimise and maintain it. The day-to-day enthusiasm and encouragement of the therapeutic team is an essential ingredient, and the patient's own awareness of progress then plays back to reinforce it. All through the programme, proper communication must be maintained so that he is aware of the plans and goals at every stage. Motivational interviewing is a specific technique that was originally designed to help patients with addictions, but more recently has been used in a variety of setting where poor motivation may jeopardise improvements in health. In an RCT, weekly sessions of motivational interviewing over 4 weeks on a rehabilitation unit after stroke were found to improve mood at 3 months, but not to have any impact on disability scores (Watkins *et al.* 2007).

A watch must be kept for evidence of depression, which may well respond to appropriate medication or psychological therapy. Tactful handling may be required in the face of discouragement, withdrawal or obstinacy. Clear guidelines must sometimes be drawn up, especially for patients with intellectual impairment who will benefit from a structured environment. In contrast, flexibility must be built into the programme to allow for patients with differing needs and personalities. Rigid conformity to set standards cannot always be expected, and in some persons will be counterproductive.

Attention must also be devoted to the relatives of the patient. They too will need full discussion of aims and procedures, and help in adjusting to the disabilities that are likely to remain. Careful physical rehabilitation may be doomed to failure if insufficient attention has been given to the family situation and to the impact of the problem on family members. Here the social worker has a vital part to play, and should be brought into the picture at an early stage. Much time may be needed to allay unrealistic expectations or needless anxieties and fears. The stroke and its repercussions may have had a far-reaching effect on many members of the household, disturbing the family equilibrium and requiring a reorganisation of roles. Preparations for discharge must be made well in advance, on a practical as well as an emotional level. The patient's assets and liabilities must be carefully assessed, likewise the family and community resources available to help. Physical adaptations may be needed in the home by way of ramps or simple supports. Proper liaison will be required with local authority and voluntary services. Where work is being considered, extended evaluation and retraining will often be indicated. Sheltered employment may need

to be found when the patient is too disabled to cope on the open market.

In older patients, and those severely disabled, attendance at a day centre or social centre may need to be organised. Transport problems in particular will need attention. For those who remain at home every effort must be made to combat feelings of loneliness and isolation, by building new contacts, encouraging a return to hobbies and mobilising community resources.

Sadly, some patients will need to remain in institutions, usually by virtue of extensive mental impairments in addition to their neurological defects. Others will have complicating pathologies, such as heart disease or arthritis, which have conspired to make effective rehabilitation impossible. Here nursing care and occupational therapy will be required long term in order to maintain a reasonable quality of life. Adequate stimulation must be ensured, with routines that are as varied and congenial as possible. Psychotropic medication will occasionally be required to combat anxiety and depression.

Subarachnoid haemorrhage

It is estimated that subarachnoid haemorrhage, with an incidence of about 6–7 per 100 000 per year in most populations, makes up some 5% of cerebrovascular accidents (van Gijn *et al.* 2007). It is particularly important because, even though the incidence increases with age, it affects a younger age group than other strokes; half of patients with subarachnoid haemorrhage are less than 55 years old. Reduced level of consciousness on admission is one of the best predictors of poor outcome. The World Federation of Neurosurgical Societies (WFNS) scale for grading subarachnoid haemorrhage is therefore based heavily on the Glasgow Coma Scale (GCS), starting at grade I, defined by a GCS score of 15 and no motor deficit, and ending at grade V, defined by a GCS score of 3–6 with or without motor deficit (Teasdale *et al.* 1988). The mortality rate is high; about half of cases die. Nevertheless, correct management can substantially reduce mortality. In about 80% of cases subarachnoid haemorrhage is the result of rupture of an intracranial aneurysm.

Non-aneurysmal perimesencephalic haemorrhage came to be recognised as a cause of subarachnoid haemorrhage when CT imaging allowed visualisation of the location of the subarachnoid blood. In non-aneurysmal perimesencephalic haemorrhage, which accounts for about 10% of subarachnoid haemorrhage, the blood is usually restricted to the cisterns around the midbrain (van Gijn *et al.* 1985). The headache is not as dramatic in onset as in aneurysmal rupture, clinical signs are generally mild at most and the outcome is good. The angiogram is negative and it seems likely that venous, rather than arterial, bleeding is responsible. Non-aneurysmal perimesencephalic haemorrhage has no impact on quality of life (Brilstra *et al.* 1997) and is not discussed further.

Other causes of subarachnoid haemorrhage include ruptured angiomas, bleeds from intracranial and spinal tumours, blood dyscrasias or inflammatory conditions of the brain and meninges. Some represent primary intracerebral or cerebellar haemorrhages that have bled into the ventricular system and thereby reached the subarachnoid space. A table of rare causes of subarachnoid haemorrhage can be found in the review by van Gijn *et al.* (2007).

Aneurysms arise from defects in the media, usually at the forks of the cerebral arteries. The great majority arise close to the circle of Willis at the base of the brain. Common sites are on the anterior cerebral or anterior communicating arteries, at the point of division of the middle cerebral arteries, or where the posterior communicating artery arises from the upper end of the internal carotid artery. Rupture occurs spontaneously and suddenly, with bleeding directly into the subarachnoid space and often into the adjacent brain substance as well. Most ruptured aneurysms are less than 1 cm in diameter. Another common site for intracranial aneurysms is the intracavernous part of the internal carotid, but aneurysms here more often lead to local pressure effects than to subarachnoid haemorrhage (see below).

Intracranial aneurysms steadily become more common with age such that they are present in about 2% of adults. In the vast majority of cases these aneurysms will never rupture. It may therefore be difficult to estimate whether the risks of preventive treatment of an aneurysm found incidentally, during cerebral imaging for some other purpose, outweigh the benefits of any reduced risk of rupture; useful guidance is to be found in a recent meta-analysis of the risk (Wermer *et al.* 2007a). In a study of patients with previously treated aneurysm, those who were subsequently found to have a further silent aneurysm that was then left untreated did not seem to suffer adverse psychological effects (van der Schaaf *et al.* 2006). There is therefore an argument for the importance of doing nothing for silent aneurysms (Brainin 2006). On the other hand, when subjects with a strong familial history of aneurysmal subarachnoid haemorrhage are screened, those found to have a silent aneurysm then have worse psychosocial outcome than those who screen negative (Wermer *et al.* 2005a). A recent study found that elective surgery improved quality of life in patients in whom an unruptured intracranial aneurysm had been found incidentally (Yamashiro *et al.* 2007).

Risk factors for subarachnoid haemorrhage include smoking, hypertension and drinking alcohol to excess, as well as having a larger aneurysm. In about 20% of cases activity, including physical exertion or sexual intercourse, seems to have precipitated rupture of the aneurysm. In about 10% of cases the subarachnoid haemorrhage is familial, in which case large and multiple aneurysms are more frequent. Genetic factors have not been identified, although those with autosomal dominant polycystic kidney disease are at high risk.

Acute clinical picture and management

The onset is abrupt with intense, often catastrophic pain in the head, mainly in the occipital region but radiating into the neck and later becoming generalised. Vomiting, photophobia and fits may occur and onset may be complicated by cardiac arrest in a small minority. Consciousness may be lost from the outset and about one-third of cases present in coma, although some patients retain full awareness throughout. Others are drowsy, confused and irritable. Sometimes the mental symptoms overshadow the headache to such an extent that the diagnosis is not immediately apparent. From a case series of over 700, nine cases were identified who presented with delirium (Reijneveld *et al.* 2000). Only three cases had headache and only three had witnessed loss of consciousness. Although four of the cases had an anterior communicating artery (ACoA) aneurysm and five had hydrocephalus, it was not possible to identify any definite predictors of delirium. One study of 66 patients within 4 days of subarachnoid haemorrhage found that 11 (16%) fulfilled criteria for delirium (Caeiro *et al.* 2005). These 11 patients with delirium were more likely to have intraventricular bleeding and hydrocephalus, and to be older; two of them had bifrontal haematoma. There have been several case reports over the years of subarachnoid haemorrhage presenting with behavioural change including akinetic mutism, delusional misidentification or an amnesic-confabulatory syndrome (Mobbs *et al.* 2001). In some cases the patients were accused of drunkenness at the onset or of being hysterical (Walton 1956). Very occasionally a patient will present with amnesic symptoms akin to transient global amnesia.

A man in his early fifties presented with headache and vomiting which started in the morning. During the course of the day he developed a state, lasting several hours, during which he repetitively asked what has happened, saying that he could not remember anything. There was no loss of personal identity. Subsequently a diagnosis of subarachnoid haemorrhage from an ACoA aneurysm was made, and the angiogram showed spasm of the anterior cerebral arteries. He later underwent surgery but his postoperative recovery was complicated by hydrocephalus. He was left with a severely disabling Korsakoff syndrome (see below), which was associated with numerous bizarre confabulations and delusions, for example the belief that surgically implanted small metal arrows were in his brain and were coming out through his ear. These confabulatory delusions gradually resolved over many months. He was left with a severe amnesic state, but was nevertheless by 2 years after the haemorrhage, perhaps aided by treatment with donepezil, able to live by himself with a little support from his family.

Neck stiffness generally becomes intense but is not always present. Papilloedema may develop immediately or within a few days, and subhyaloid haemorrhages may be observed spreading from the edges of the optic discs. Focal ophthalmoplegias are common, and aphasia or hemiplegia may result from arterial spasm or intracerebral extension. Rupture of ACoA aneurysms may damage basal forebrain, which lies immediately above the aneurysm. Localising signs are often absent but ischaemia can be extensive in one or both frontal lobes, presumably due to occlusion or spasm of the anterior cerebral arteries. Middle cerebral artery aneurysms lie in the sylvian fissure or embedded in the frontal or temporal lobes nearby. Rupture is often accompanied by hemiparesis due to vascular spasm in the territory of the middle cerebral artery or haematoma formation. Posterior communicating aneurysms lie medial to the uncus of the temporal lobe. They often bleed directly into the subarachnoid space, but infarction can be widespread in the territory of the middle cerebral arteries, and there may also be interference with the fine perforating vessels to the basal ganglia and hypothalamus.

During the first few days, subarachnoid blood is generally visible as high signal on routine brain CT, which is therefore the critical initial investigation. Lumbar puncture is now restricted to those cases, about 3%, with a typical clinical picture but no evidence of subarachnoid blood on CT. Conventional cerebral angiography is the definitive investigation; however, using this as the gold standard, CT angiography can now achieve about 95% sensitivity for identification of aneurysms and has the advantage of being much less invasive and with less likelihood of complications.

Immediate bed rest is mandatory, with sedation, analgesics and good general nursing and medical care. Even at this early stage psychological support for the family and patient is helpful. One study has looked at the value of a specialist liaison nurse on the neurosurgical unit (Pritchard *et al.* 2004). The nurse was a senior neurosurgical ward nurse whose role was to support and counsel patients with subarachnoid haemorrhage and their families. Once the liaison nurse was in place, the progress of a cohort of patients admitted over a 2-year period was compared with a cohort of patients admitted over the previous 18 months. At 6 months after discharge the patients who had access to the specialist liaison nurse showed better emotional adjustment and confidence, and greater satisfaction with their inpatient treatment.

In the early days after subarachnoid haemorrhage, once the diagnosis has been established, there are three main considerations: (i) minimise the risk of rebleeding, (ii) try to prevent delayed cerebral ischaemia, and (iii) manage any hydrocephalus. Rebleeding is the major cause of poor outcome; without intervention more than one-third of patients will rebleed within the first few weeks. This risk can be reduced by surgical intervention, but in the past this necessarily involved a craniotomy and surgical clipping of the aneurysm and the threat of aggravating cerebral ischaemia.

Over the last few years clipping has largely been replaced by coiling of the aneurysm using an intra-arterial catheter. Once the end of the catheter is in place in the aneurysm, small platinum coils are detached to rest in the aneurysm which then becomes occluded by reactive thrombosis. There is a chance of the aneurysm subsequently reopening and some clinicians regard long-term follow-up angiography as mandatory (Feigin & Findlay 2006). In a large RCT comparing coiling to clipping, largely restricted to patients in good clinical condition with small aneurysms of the anterior circulation, coiling was significantly less likely to be associated with poor outcome at 1 year (van der Schaaf *et al.* 2005); compared with clipping, the number needed to treat to prevent one poor outcome was 15. The advantage of coiling, in terms of survival, was maintained at 7-year follow-up (Molyneux *et al.* 2005). Platinum coils also have the advantage over many neurosurgical aneurysmal clips in that they are non-magnetic and patients can therefore undergo MRI subsequently. However, some aneurysms will be unsuitable for coiling because of their anatomical configuration.

Cerebral ischaemia, sometimes involving vessels at a distance from the aneurysm, is a considerable problem for many patients over the hours and days after subarachnoid haemorrhage, reaching a peak after 1–2 weeks. Infarcts, usually involving the cortex, may be found in almost 40% of patients (Rabinstein *et al.* 2005). In some they are single infarcts often near the aneurysm but in others multiple infarcts at a distance from the site of rupture are seen. Patients with a large amount of subarachnoid blood or with loss of consciousness are at increased risk. Vasospasm may be partly to blame, but global ischaemia and hypotension are contributory factors. Treatment with calcium antagonists, in particular nimodipine for 3 weeks, reduces the risk of poor outcome (Rinkel *et al.* 2005) and is now standard practice.

Hydrocephalus may develop at any time after subarachnoid haemorrhage. Usually it develops in the acute phase, in the hours after the haemorrhage. However, not all patients with ventriculomegaly on the acute CT scan will need shunting because in about half there will be spontaneous improvement (Hasan *et al.* 1989). Shunting should be restricted to those with good clinical evidence of need and be for as short as possible, because of the risk of ventriculitis. Nevertheless, the clinician needs to remember that hydrocephalus may be a cause of deterioration in mental state, months or years after haemorrhage.

In the long term perhaps 2–3% of patients will rebleed over the 10 years after surgical clipping for subarachnoid haemorrhage (Wermer *et al.* 2005b) and the figure is not much different for coiling (Sluzewski *et al.* 2005). Epilepsy is seen in about 5% of cases in the first year, being more common in those with worse WFNS grading and worse outcome. Coma persisting for more than 24 hours is a bad prognostic sign. Axonal damage, assessed using neurofilament levels in ventricular cerebrospinal fluid (CSF) over the first few days, may con-

tribute to poor outcome (Petzold *et al.* 2006). With modern management some two-thirds of patients may be expected to survive a first bleed, although one-third of survivors will be left with major neurological disability. In patients with no aneurysm demonstrable on angiography the mortality and morbidity rates are considerably lower. High levels of pituitary deficiency have been found after subarachnoid haemorrhage and it has been suggested that this may contribute to chronic symptoms in a proportion of cases (Kreitschmann-Andermahr *et al.* 2004).

Psychiatric sequelae of subarachnoid haemorrhage

Severe, but usually transient, confusion and states of akinetic mutism can be seen in the early stages of recovery. The later sequelae, after 2–11 years, were described by Walton (1952, 1956) among 120 survivors. Important residua included persistent headache in 23%, organic mental symptoms in 9% and anxiety symptoms in 27%. The anxiety was occasionally severely disabling, resulting in chronic psychiatric invalidism.

Subsequently, two large series of patients were reported with attention directed primarily at the psychiatric sequelae. Storey (1967, 1970, 1972) studied 261 patients who had suffered a subarachnoid haemorrhage 6 months to 6 years earlier, noting the site of the responsible aneurysm and correlating this with the psychiatric aftermaths; 81 patients had bled from ACoA aneurysms, 71 from middle cerebral aneurysms, 72 from posterior communicating aneurysms and seven from multiple aneurysms, while in the remaining 30 no aneurysm could be detected. Logue *et al.* (1968) confined attention to 79 survivors of haemorrhages from anterior cerebral aneurysms, studied 6 months to 8.5 years later. Both studies confirmed the high incidence of mental disablement among survivors, especially as a result of organic mental impairments and personality change attributable to brain damage. Rather surprisingly both also stressed that, compared with how the survivor had been before the haemorrhage, improvement in personality could occasionally occur, mainly evident to relatives but sometimes also to the patients themselves.

Cognitive impairments including amnesia and confabulation

Storey (1967) found persistent intellectual difficulties in about 40% of patients as judged by simple clinical criteria. They were rated as moderate to severe in some 10% of cases, and occasional patients remained grossly demented and bedridden. Those with middle cerebral aneurysms fared considerably worse than other groups, while patients with no demonstrable aneurysms had the lowest morbidity of all. In the study by Logue *et al.* (1968), patients with anterior cerebral aneurysms showed 10% with global dementia but many

more with minor persistent deficits; 40% showed dysphasic errors on detailed testing. Memory was often more impaired than intelligence. Further studies have demonstrated cognitive impairments even in survivors of subarachnoid haemorrhage who have had good outcome (Hutter & Gilsbach 1993; Mayer *et al.* 2002), although not all studies find evidence of impairment (McKenna *et al.* 1989). Predictors of worse cognitive outcome include lower GCS score on admission and ventricular enlargement (see table 4 of Haug *et al.* 2007) and the presence of large amounts of subarachnoid blood; those with left-sided infarction may be most affected (Hutter *et al.* 2001; Kreiter *et al.* 2002).

Executive function, memory and speed of information processing seem to be most vulnerable. For example, when 20 patients with ACoA aneurysms were compared with 17 with aneurysms of other branches of the internal carotid artery on a neuropsychological test battery at least 6 months after subarachnoid haemorrhage, no differences between the two groups could be found (Tidswell *et al.* 1995). However, in both groups, compared with controls, there were deficits on executive function and in memory. Cognitive impairment improves over the first year (Samra *et al.* 2007). Nevertheless, long-term cognitive deficits are found, for example as late as 7 years (Stenhouse *et al.* 1991). However, subjective complaints of memory problems or absent-mindedness may have more to do with patients' dissatisfaction with their situation, in particular social support, than with objective evidence of cognitive impairment (Toomela *et al.* 2004).

Most of the patients studied in the papers reviewed above underwent surgical clipping of the ruptured aneurysm. It is therefore reasonable to ask how much of any cognitive impairment present months and years after haemorrhage is due to the immediate effects of the aneurysm and how much to the surgery to clip the aneurysm. This was assessed by testing 27 patients in good condition while on the neurosurgical unit after the haemorrhage but before surgery, and then again after they had recovered from surgery and many months later (Maurice-Williams *et al.* 1991). In the majority of patients there was no evidence of an adverse effect of surgery on cognitive performance, with the exception of two patients with definite surgical complications.

More recent studies have considered whether clipping or coiling produces less cognitive impairment. Four non-randomised studies have looked at outcomes over the first year following treatment of patients with either clipping or coiling. In the largest study ($N = 40$ in each arm matched for severity of the haemorrhage), there was a trend for greater impairment in the group treated surgically with clipping (Hadjivassiliou *et al.* 2001). This seemed to be confirmed by two smaller studies which found that those treated with coiling had less impairment of executive function and memory (Chan *et al.* 2002; Fontanella *et al.* 2003). However, another small non-randomised study found in favour of

clipping, although this effect disappeared once National Adult Reading Test (NART) estimates of premorbid IQ were taken into account, leaving both groups showing equivalent impairment (Frazer *et al.* 2007). Furthermore, in none of these studies were patients randomised to receive coiling or clipping, and therefore the findings could have more to do with factors that governed whether an aneurysm was clipped or coiled rather than which procedure was in fact used. The most rigorous study is therefore an RCT of 109 patients randomly assigned to either surgical treatment (clipping) or endovascular treatment (coiling) (Koivisto *et al.* 2000). No differences between the two groups on neuropsychological testing at 3 or 12 months were found.

In conclusion, when it comes to neuropsychological outcome the evidence that clipping is worse than coiling is not very strong, but there is certainly very little to suggest that clipping is better. However, there is good evidence that patients treated with coils have less evidence of damage on MRI; 45% of clipped patients showed lesions consistent with superficial brain retraction on MRI, whereas only 10% of coiled patients did, and surgically treated patients also had more ischaemic lesions in the territory of the parent artery (Koivisto *et al.* 2000). Likewise, in one of the non-randomised studies referred to above, it was only in the clipped group that there was evidence of focal encephalomalacia, presumably due to the effects of the surgery itself (Hadjivassiliou *et al.* 2001).

Although some studies have found that those with ACoA aneurysms do worse (Bornstein *et al.* 1987; Kreiter *et al.* 2002), in general it has been surprisingly difficult to demonstrate that the site of the aneurysm has a bearing on neuropsychological outcome (Desantis *et al.* 1989; Richardson 1991; Ogden *et al.* 1993; Tidswell *et al.* 1995). For example, in a recent RCT of the effects of hypothermia on outcome after surgical clipping of subarachnoid haemorrhage, over 150 patients with good outcome (good outcome or moderate disability on the Glasgow Outcome Scale) were tested at 9 and 15 months across a range of cognitive tests (Samra *et al.* 2007); 25% of patients showed cognitive impairment, defined as two standard deviations below the mean of the control population on a composite cognitive test score, with a trend toward a smaller proportion being impaired at 15 months. However, the location of the aneurysm did not affect the proportion demonstrating cognitive impairment, nor did treatment with hypothermia.

However, these findings contrast with the literature, and anecdotal experience, which suggests that ACoA aneurysms are particularly associated with severe executive and memory impairment in some cases, producing a Korsakoff syndrome of amnesia, disorientation, poor insight and confabulation (DeLuca & Diamond 1995). This evidence is based heavily on case studies (Volpe & Hirst 1983; Parkin *et al.* 1988) and case series showing that memory impairment is common in patients with ACoA aneurysms (Gade 1982; Alexander &

Freedman 1984; Laiacona *et al.* 1989; Stenhouse *et al.* 1991). For example, Lindqvist and Norlén (1966) reported amnesic syndromes in 17 of 33 patients after operations on ACoA aneurysms. Eleven improved markedly within 6 months, but five appeared destined to be permanent. Transient confabulation was noted in almost one-quarter of Logue *et al.*'s (1968) cases and two striking examples of enduring memory difficulties have been reported after operative intervention on ACoA aneurysms (Sweet *et al.* 1966; Talland *et al.* 1967).

Preoperatively both patients had been confused and apathetic, but immediately postoperatively they showed severe disorientation, non-sensical confabulation, and some retrograde and virtually complete anterograde amnesia. The disorientation improved considerably within a few weeks, and at the same time their confabulation changed from fantastic fabrications to temporal misplacement of actual incidents. Over the next 3 years the memory disorder became chronic, together with impotence and lack of initiative. The lesions seen at operation had involved the posteromedial aspects of the orbital surface of both frontal lobes and the adjoining medial surface of the hemispheres, the so-called septal region in front of the lamina terminalis and anterior commissure. The crucial region was thought to lie in the septal region bilaterally.

Others have also suggested that damage to basal forebrain (septal nuclei, substantia innominata, nucleus accumbens, anterior hypothalamus) is responsible for the amnesia (Damasio *et al.* 1985). This is consistent with the CT findings of Vilkki *et al.* (1989); patients with medial frontal infarcts, which were usually due to ACoA aneurysms, were more likely to have memory impairments than those with infarcts in other locations.

Why is it that the rigorous cases series described above so often fail to demonstrate a particular relationship of ACoA aneurysm to amnesic disorder? It is probably because Korsakoff's syndrome is a relatively uncommon, though specific, outcome of ACoA aneurysm rupture. If only one in ten patients with an ACoA aneurysm develops an 'ACoA syndrome' with confabulation and severe amnesia, then in any small case series this effect may easily be swamped by other cases with ACoA aneurysm with non-specific heterogeneous outcomes similar to those with aneurysms in other locations. The problem is nicely demonstrated in the study of Bottger *et al.* (1998). In this consecutive series of 30 patients tested some months after ACoA aneurysm, the full Korsakoff syndrome of disorientation, confabulation, amnesia and lack of insight was only seen in three cases. The other cases showed various degrees of executive and memory and attentional problems, probably rather similar to the impairments seen with other aneurysm locations. It is also worth noting that the three Korsakoff cases all had Glasgow Outcome Scale ratings of 3 (severe disability). These cases would therefore never have appeared in several of the studies described above, which only studied patients with good outcome or moderate disability. It may also be the case

that now coiling is replacing clipping, the ACoA syndrome will be less frequently seen.

There are probably several pathogenic factors that cause disruption of basal forebrain after ACoA aneurysm rupture, producing the amnesic syndrome: hydrocephalus (Theander & Granholm 1967), cerebral vasospasm (Volpe & Hirst 1983; Weidauer *et al.* 2007), interference with the small perforating arteries at operation (Gade 1982), and haemorrhage directly from the aneurysm into the brain tissue immediately above. The observation that in some cases there is a latent interval of several days before the syndrome appears, followed by spontaneous recovery usually over a few weeks (Tarachow 1939; Walton 1953), is compatible with the effects of either hydrocephalus or cerebral vasospasm.

Donepezil may improve memory function in patients with basal forebrain damage due to subarachnoid haemorrhage. Eleven such patients, mostly with ACoA aneurysms, with a chronic amnesic syndrome lasting at least 1 year and tested on average over 6 years after the haemorrhage, were offered donepezil in an open study over a period of 12 weeks (Benke *et al.* 2005). Compared with their performance on tests of memory at baseline, improvements were seen after 12 weeks of donepezil whereas there were no significant effects on tests of attention or executive function. Four weeks after drug discontinuation there was a significant drop in memory performance. No measurements of disability were made, to see if these changes on tests of memory impairment translated into reductions in disability.

Personality changes

Personality deterioration after subarachnoid haemorrhage usually has an obvious organic stamp and occurs in a setting of intellectual impairment. Prominent changes include loss of drive and vitality, decreased interest and initiative, withdrawal, irritability and easily provoked anxiety. Emotional lability and catastrophic tendencies may be marked. Storey (1970) described a picture of 'organic moodiness' with chronic shallow depression, often lifting in response to some new stimulus but rapidly falling back again with boredom, loss of interest and easy fatigue. Changes reminiscent of the frontal lobe syndrome may occur, with uninhibited selfish behaviour, tactlessness, elevation of mood and a decreased tendency to worry. Some of these latter aspects can be construed as improvements in personality, as discussed below.

Personality impairment was rated as moderate or severe in 19% of Storey's patients, and mild in 22% more. It was most common after rupture of middle cerebral aneurysms, and in general the incidence paralleled that of intellectual impairment and neurological disability. The exception was a significant tendency for patients with ACoA aneurysms to show relatively less intellectual impairment in the presence of personality deterioration. Descriptions of disinhibited behaviour, lessened worry and lessened irritability were commoner in those with anterior aneurysms than other

groups, lending support to the classic idea of a frontal lobe syndrome. In an attempt to define any decision-making deficits that might be responsible for the personality change, patients with ACoA aneurysms have been tested on a gambling task. As a group they showed increased risk-taking behaviour (Mavaddat *et al.* 2000), possibly due to disruption of orbital prefrontal cortex. On the other hand, using the same task a rather different pattern of responding was found in survivors of middle cerebral or posterior communicating artery aneurysms. They showed altered sensitivity to both reward and punishment, and impulsive responding (Salmond *et al.* 2006). However, neither study measured whether there was in fact any personality change in the individuals tested.

Improvement in personality was noted by relatives in 13 of Storey's patients, eight after bleeds from anterior aneurysms. The same was seen in nine of Logue *et al.*'s (1968) patients. In both series, therefore, approximately 10% of patients with anterior bleeds showed a favourable outcome of this nature. Storey's patients were described as being more pleasant to live with, less sarcastic and irritable, less anxious and fussy, and often more affectionate and tolerant. Most were aware of increased well-being subjectively. The majority had previously been tense, perfectionistic or inhibited. Two who had been gloomy and readily fatigued became cheerful, vigorous and lost their tension headaches. Another lost compulsive rituals of long standing. Two of the 13 showed minor forgetfulness, but in the remainder there was no detectable intellectual impairment. None showed loss of drive or fall-off in work ability. A more recent study found that 13% of patients reported a positive personality change, although the paper gives no further description of what was meant by this (Wermer *et al.* 2007b).

However, Logue *et al.* (1968) found that a price was usually paid for the improvements, in terms of memory impairment or an increase in irritability or outspokenness. The improvements consisted mainly of a decreased tendency to worry or get depressed. In three patients there was relief of pre-existing endogenous depression, and another showed virtual relief of an obsessional neurosis. Both Storey and Logue attributed the improvements to a 'leucotomy effect' consequent on frontal lobe damage or ischaemia.

Anxiety and depression

Walton (1952) emphasised anxiety symptoms in 27% of his cases, half with premorbid neurotic tendencies and half without. The anxiety was often severe and incapacitating, centring largely on fear of recurrence of the haemorrhage. Some patients were afraid for months afterwards to leave the house, or retired to bed immediately they had a headache. In some instances the situation had been worsened by medical advice to avoid exertion.

Storey (1972) found symptoms of anxiety or depression in one-quarter of patients, being moderate or severe in 14%.

Such symptoms showed an association with indices of brain damage, but depression could also be severe when there was no evidence of brain damage whatever. The depressives without neurological signs had been more neurotic and prone to depression in their premorbid personalities, while those with brain damage had more often been energetic and were therefore perhaps reacting to their loss of function. The patients in whom aneurysms had not been detected appeared to form a special group, with a similar incidence of depression to the remainder despite considerably less evidence of intellectual impairment or neurological disability. Depression was commonest of all, and more liable to be severe and persistent, in patients with posterior communicating aneurysms, where rupture is known to interfere with the fine perforating vessels to the hypothalamus.

More recently, three studies have relied on the HADS to determine symptoms of depression and anxiety. Using a score of greater than 10 on the HADS as a cut-off, indicating that the patient was at least 'probably depressed', 8.5% (9 months after haemorrhage, good to fair outcome patients only) (Powell *et al.* 2002), 17% (on average at 16 months) (Morris *et al.* 2004) and 9% (2–19 years) (Wermer *et al.* 2007b) were identified as probably depressed. Almost twice as many scored above 10 on the anxiety scale of HADS, the figures being 17%, 38% and 11% respectively. However, using the Beck Depression Inventory (BDI) and the State Trait Anxiety Inventory (STAI), Fontanella *et al.* (2003) failed to find significantly elevated scores for depression or anxiety compared with controls in patients with good outcome assessed 6 months after subarachnoid haemorrhage.

It has been suggested that post-traumatic stress disorder (PTSD) is quite a common sequelae. In a survey of 28 patients referred to a neuropsychology clinic after subarachnoid haemorrhage, almost one-third of patients were assessed as meeting diagnostic criteria for PTSD (Berry 1998). This finding receives some support from Powell *et al.* (2002). Patients were recruited consecutively at the time of haemorrhage and rated themselves on the Revised Impact of Events Scale at 3 and 9 months; 30% of patients scored in the clinical range on both subscales (intrusive thoughts and avoidance) at 3 months, falling to 15% at 9 months. At 18 months, three of the patients seemed to be cases of PTSD (Powell *et al.* 2004). However, none of the 63 patients studied by Rodholm *et al.* (2002) (see next section) were found to fulfil criteria for PTSD.

Other disturbances

Psychotic developments appear to be rare. Storey (1972) found no examples of psychosis among 261 patients who were studied closely from the psychiatric point of view. One of his patients developed schizophrenia a year later, but the illness seemed unrelated to the haemorrhage.

'Neurasthenic' symptoms can occasionally be marked, with fatigue, headache, dizziness and sensitivity to noise.

These were persistent and incapacitating in 7 of 56 patients followed by Theander and Granholm (1967), and present in mild degree in many more. Their origin was obscure and showed no relation to the duration of loss of consciousness. Walton (1952) commented on the general similarity between such symptoms after subarachnoid haemorrhage and after head injury, an observation that others have made (Hellawell & Pentland 2001).

At this point it is worth reviewing the studies of Rodholm *et al.* (2001, 2002) who prospectively studied a cohort of 63 patients over the first year after haemorrhage. At 3, 6 and 12 months every patient was assessed by psychiatric interview and classified according to a somewhat idiosyncratic classification of organic mental disorders developed in Sweden (Lindqvist & Malmgren 1993). So, for example, at 6 months three were found to have an emotional-motivational blunting disorder (EMD), 11 had Korsakoff's amnesic disorder (KAD) and 29 (49%) had astheno-emotional disorder (AED). The authors demonstrated that EMD and KAD were related to injury severity, as measured by conscious level on admission at the time of the haemorrhage, whereas AED was not. Of those with either EMD or KAD at 1 year, two-thirds were at least very drowsy or very confused on admission. In contrast, four-fifths of those with AED were alert or at most drowsy or confused on admission, a proportion that was not very different from the whole cohort. Patients with AED were likely to improve over the first year, the proportions at 3, 6 and 12 months being 60%, 49% and 38% respectively. However, in almost all those who had EMD or KAD at 3 months, it was still present at 1 year.

Rodholm *et al.* (2001) went on to describe AED in more detail in those who did not have evidence of either EMD or KAD or 'non-organic psychiatric disorder'. Thus the excluded patients included six who were diagnosed as suffering a non-organic psychiatric disorder usually on the basis of depressive symptoms that were either present before the haemorrhage or only appeared during the course of the first year, not having been present at 3 months. In this select sample studied at 1 year, of whom one-third were diagnosed as AED, common symptoms included fatigue, concentration impairment, memory difficulties, sound sensitivity, emotional instability and irritability. This constellation is very similar to that found in post-concussion syndrome.

Therefore a picture emerges which is reminiscent of that seen in traumatic brain injury. Some neuropsychiatric sequelae, for example personality change with disinhibition or poor motivation, and the amnesic syndrome, are tightly determined by the severity of brain injury. In contrast, patients also suffer a range of symptoms, of which fatigue, headache, dizziness and emotional changes are the commonest, that are less easy to understand simply as a consequence of brain injury, more likely to improve over the early months, and probably more related to psychological factors.

Psychosocial and long-term outcome

One year after subarachnoid haemorrhage almost 50% of survivors report incomplete recovery. This was the finding in a population-based study of over 200 patients, comprising 95% of the target cohort, who were available for telephone interview between 12 and 18 months after haemorrhage; 50% reported memory problems, 40% mood problems and 10% reported being dependent in terms of everyday activities (Hackett & Anderson 2000). On the SF-36 assessment of quality of life, patients reported significant restrictions in work and other activities.

Even when studies are restricted to patients with good neurosurgical outcome, many are found to have disabling psychosocial problems that relate to cognitive, emotional and behavioural sequelae. Three studies have restricted their ascertainment to patients rated good or fair outcome on the Glasgow Outcome Scale. In one study the majority of patients, examined at 1–5 years, nevertheless reported restrictions in the domains of motivation and/or mental capacity and/or social relationships (Hutter *et al.* 1995). They tended to suffer worse headaches than before the haemorrhage, almost one-third were depressed, and almost one-third reported that they had lost their job or been demoted or retired. In a second study, only 3 of 20 patients fully employed at the time of the haemorrhage were still employed at that level 19 months later (Buchanan *et al.* 2000). Common symptoms were high levels of fatigue and intolerance of noise and social contact. Reduced libido was seen in over half. Very few reported positive effects of the injury and family members reported that they themselves had high levels of distress and burden. Finally, in their study of 52 patients recruited consecutively and compared with controls matched carefully for age, sex and psychosocial status, Powell *et al.* (2002) demonstrated the lowered levels of social participation 9 months after subarachnoid haemorrhage. On measures of self-organisation and productive employment, over half the patients scored above the 90th centile of the control population scores (i.e. were less active). There was subtle evidence of cognitive impairment, with greater impairment evident at 3 months than 9 months, by which time only prose recall was impaired. Elevated levels of depressed mood, intrusive thoughts and avoidance were reported (described above).

Most of the improvement in disability takes place over the first year. Using the 8-point extended Glasgow Outcome Scale to measure disability on several occasions over the first 5 years, it was possible to demonstrate significant improvements in outcome (e.g. from severe disability to moderate disability) in the first 6 months (Svensson & Starmark 2002). However, after 12 months and over the next 4 years patients were as likely to deteriorate one point as they were to improve one point, with the vast majority of patients remaining unchanged.

It is therefore not surprising to find that symptoms remain in the long term. A postal survey of relatives of patients with

subarachnoid haemorrhage or traumatic brain injury who had been admitted to a neurosurgical unit 5–7 years before found that they frequently reported that the patient had symptoms of impatience, passivity or tiredness (Hellawell & Pentland 2001). There was a considerable degree of overlap in the symptoms described by the two groups. Another study examined outcome 4–7 years after haemorrhage and found similar problems, but gained the impression that the cohort had improved over the years and many had a positive attitude to life (Ogden *et al.* 1997). For example, more than 75% of subjects reported that though they had for several months or years after the haemorrhage suffered fatigue or sleepiness, these had now resolved. The largest study is of over 600 patients most of whom had at most slight disability after a subarachnoid haemorrhage between 2 and 19 years (average 9 years) previously (Wermer *et al.* 2007b). At interview patients were asked about symptoms and handicap. One-quarter of patients who had been working before the haemorrhage were no longer working, and a further one-quarter were working reduced hours or in a less demanding position. Almost 60% reported personality change, the commonest changes being increased agitation/irritability, increased emotionality and apathy. Overall 35% reported memory problems, although the proportion lessened as time since haemorrhage increased. The most frequent symptoms were fatigue, headaches, concentration problems and dizziness, with only one-quarter of patients saying that they had made a complete symptomatic recovery. Thus the pattern and extent of problems, compared to what has been described above in the first months and years after haemorrhage, does not seem to change much in the very long term.

Emotional precipitation of subarachnoid haemorrhage

Occasional examples are reported of cerebrovascular accidents that show a striking temporal relationship to emotionally stressful events. However, the most dramatic instances appear to involve patients with subarachnoid haemorrhage. Particularly striking examples have been recorded by Storey (1969, 1972), in which the haemorrhage followed immediately upon some emotionally traumatic event, presumably by virtue of the rise of blood pressure engendered. Thus a woman answered the door to a policeman who told her that the woman next door, her closest friend, had hanged herself: she said ‘Oh, my God’ and forthwith had her haemorrhage. Another woman was watching television when an aeroplane on a test flight was shown exploding in the air; she believed (erroneously as it turned out) that her son was on it, put her hands to her head and had the haemorrhage within seconds of the disaster. Another had a subarachnoid haemorrhage within a minute of being told by her husband that he knew of her adultery and was going to divorce her.

Altogether Storey found evidence of a striking emotional precipitant in four of his original 261 patients, and two further less dramatic examples. All were in women, although 43% of the series were male. Such precipitation appeared to be markedly more common in patients with no obvious source for the haemorrhage than in patients with aneurysms demonstrable on angiography. On the other hand, Powell *et al.* (2002) found no evidence of higher stress levels, from self-report after the event, in patients with subarachnoid haemorrhage compared with controls.

Giant cerebral aneurysms

The great majority of aneurysms giving rise to subarachnoid haemorrhage are small, rarely exceeding 1 or 2 cm in diameter. Massive aneurysms are distinctly uncommon, but when present can give rise to much diagnostic confusion and are often not even considered in differential diagnosis.

Best known is aneurysm of the intracavernous portion of the internal carotid artery, which may compress surrounding nerves leading to ophthalmoplegias and sensory loss of trigeminal distribution. They most commonly present with diplopia and pain in the face, eye or head (Stiebel-Kalish *et al.* 2005). Occasionally, they rupture to give rise to a carotid-cavernous fistula that may produce pulsating exophthalmos and a bruit.

Those situated on the circle of Willis at the base of the brain rarely rupture, but can produce local pressure effects simulating basal space-occupying lesions. Bull (1969) reported 22 such cases collected over a similar number of years. Common complaints were of visual disturbance or headache. However, in six patients mental changes predominated; dementia was the presenting feature, usually but not invariably accompanied by neurological signs such as cranial nerve deficits or hemiparesis.

Morley (1967) reviewed the literature concerning unruptured vertebrobasilar aneurysms, which can lead to a variety of pictures simulating multiple sclerosis, posterior fossa tumours or vertebrobasilar ischaemia. Three of his own five cases had at first been diagnosed as psychiatrically unwell; vague symptoms of headache, nondescript dizziness, slowed speech and a muted facial expression had led to an impression of depressive illness. Mental impairment was also sometimes evident.

Hypertensive encephalopathy

This was never a common condition, with less than one in six patients with malignant hypertension suffering encephalopathy (Healton *et al.* 1982), and is even rarer now that better management of hypertension prevents the malignant phase. Nevertheless, it is still very occasionally seen, particularly in patients with eclampsia (Becker 2006). When it does arise it is always a serious medical emergency. Very occa-

sionally it may be the presenting manifestation of the hypertension.

Onset is acute with headache, drowsiness, apprehension and mental confusion. Epileptic fits frequently occur. Sometimes focal neurological signs, including cortical blindness and hemiplegia, may be found but are not usually part of the picture. Vomiting may occur and papilloedema frequently develops. The disorder evolves rapidly, often within the space of 24 hours, and if untreated progresses to coma with fatal outcome in a high proportion of cases. The diastolic blood pressure is extremely high, often exceeding 140 mmHg. Patients generally make a full recovery although three cases have been described in which hypertensive episodes in childhood appear to have been followed by temporal lobe epilepsy and hippocampal sclerosis (Solinas *et al.* 2003).

Serial images are required to differentiate the acute effects of hypertensive encephalopathy from the ischaemic demyelination of white matter, characteristically in a periventricular distribution, that is associated with chronic hypertension. One long-term sequela of hypertensive encephalopathy, found on gradient echo MRI, is evidence of numerous punctate haemorrhages (Weingarten *et al.* 1994).

Cerebral oedema, particularly involving the basal ganglia and brainstem, may be found on MRI as an acute reversible effect of hypertensive encephalopathy. Another reversible finding is high signal on T2 sequences in white matter, particularly posteriorly in the cerebral hemispheres. A single case report using diffusion- and perfusion-weighted MRI suggests that vasogenic oedema is responsible for this reversible posterior leucoencephalopathy (Sundgren *et al.* 2002). The syndrome of reversible posterior leucoencephalopathy (Hinchey *et al.* 1996) may also be associated with immunosuppressive drugs and with renal failure.

Pathological examination may reveal a normal brain, but usually there is marked oedema or petechial haemorrhages and microinfarcts. Byrom (1954) showed in the rat that with hypertension of advanced degree there was intense segmental constriction of cerebral arterioles, attributable to attempts at autoregulation that fail when the pressure exceeds a certain limit. Dilatation occurs between the constricted segments and the vessel wall is damaged, leading to hyperperfusion and cerebral oedema, which may be the essential factors underlying hypertensive encephalopathy (Skinhoj & Strandgaard 1973).

Migraine

Migraine is a common and sometimes severely incapacitating disorder. Neuropsychiatric phenomena may feature prominently in the course of the attacks. Good reviews are to be found in Goadsby (2006) and Silberstein (2004). Silberstein *et al.* (2002) provide a more detailed review of neuropsychiatric sequelae.

The syndrome of migraine is hard to delineate precisely since to some extent boundaries are blurred between this and other forms of headache, particularly tension-type headache. Migraine is a familial disorder, characterised by recurrent attacks of headache widely variable in intensity, frequency and duration, commonly unilateral, usually associated with anorexia, nausea and vomiting, and sometimes preceded by or associated with neurological and mood disturbances (Critchley 1969). Comprehensive criteria for both diagnosis and classification of migraine have been proposed by the International Headache Society (IHS) (Subcommittee IHSC 2004) (Box 8.7). The IHS classification distinguishes several types of migraine, of which the most common are migraine without aura and migraine with aura. In the presence of aura the diagnosis of migraine headache is usually unmistakable, but headache in the absence of aura may be less easy to diagnose. For headache without aura, a meta-analysis recently identified the five criteria that best predict the diagnosis of migraine, using the IHS criteria as the gold standard (Detsky *et al.* 2006):

Box 8.7 Diagnosis and classification of migraine proposed by the International Headache Society
(Subcommittee IHSC 2004)

Diagnostic criteria

- A At least five attacks fulfilling criteria B–D
- B Headache attacks lasting 4–72 hours (untreated or unsuccessfully treated)
- C Headache has at least two of the following characteristics:
 - 1 Unilateral location
 - 2 Pulsating quality
 - 3 Moderate or severe pain intensity
 - 4 Aggravation by, or causing avoidance of, routine physical activity
- D During headache at least one of the following:
 - 1 Nausea and/or vomiting
 - 2 Photophobia and phonophobia
- E Not attributed to another disorder

Classification

- 1 Migraine
 - 1.1 Migraine without aura
 - 1.2 Migraine with aura (with and without headache and including familial hemiplegic migraine and basilar-type migraine)
 - 1.3 Childhood periodic syndromes that are commonly precursors of migraine (cyclical vomiting, abdominal migraine and benign paroxysmal vertigo of childhood)
 - 1.4 Retinal migraine
 - 1.5 Complications of migraine (including migrainous infarction and migraine-triggered seizure)

- Pulsating;
- duration of 4–72 hours;
- Unilateral;
- Nausea;
- Disabling.

If a patient's headache is found to meet four or five of these 'POUNDING' criteria, then it is very likely that migraine is present. Although estimates vary quite widely, it is reasonable to conclude that over the previous year about 12% of adults will have had at least one attack of migraine. The male to female ratio is about 1 : 3 and the lifetime prevalence about 16% (Hirtz *et al.* 2007).

Clinical features

Onset is usually in childhood or early adult life, some 25% of cases beginning before the age of 10 and very few after 50. A childhood history of cyclical vomiting with abdominal pain can sometimes be traced as a precursor. Affected individuals show an increased frequency of epilepsy, Raynaud's phenomenon, stroke and affective disorders (Silberstein 2004). A family history of migraine is reported in some two-thirds of cases.

A proportion of patients report premonitory symptoms. This has been studied prospectively in 76 patients who reported having non-headache symptoms that predicted an attack (Giffin *et al.* 2003). Using patient hand-held electronic diaries that were adjusted so that entries could not be retrospectively altered or deleted, patients recorded these symptoms and whether they were in fact followed by migraine. When such symptoms were recorded in the diaries they were followed by migraine within 72 hours on 72% of occasions. The most common premonitory symptoms were tiredness, difficulty concentrating, stiff neck and irritability. Such symptoms were also very common during the attack and after. In other words, there was not a specific constellation of symptoms that only occurred during the premonitory phase, although yawning, hunger or food cravings, and increased energy were more common before than during the attack. The authors suggested that the presence of non-headache symptoms before, during and after a migraine attack were consistent with a model of migraine as an episodic dysfunction of trigeminovascular regulation, probably mediated at the level of the brainstem (see below).

Headache is the most constant element, lasting usually for 8–24 hours but occasionally several days, and varying from mild discomfort to pain of incapacitating violence. It is mostly unilateral at onset, though tending to become diffuse later in the attack. Throbbing is common, at least initially, with aggravation on coughing or jolting. Anorexia, nausea and vomiting usually develop, also photophobia and intolerance of noise. Autonomic changes may include pallor, facial oedema, conjunctival injection, abdominal distension or the passing of one or more loose stools. In attacks of any

severity the patient is usually obliged to lie down until the episode has passed.

This variety is designated *migraine without aura* (previously 'common migraine'). Difficulty will be encountered in distinguishing it from tension-type headache in certain cases. In perhaps one-third of cases (Launer *et al.* 1999) the headache is preceded by an aura, the syndrome then being known as *migraine with aura* (previously 'classic migraine') (Kirchmann 2006). Various dramatic neurological symptoms may be seen but the commonest is visual disturbance as the first indication of an impending attack. The aura usually builds up over 5–20 minutes, lasts some 10–60 minutes and subsides as the headache sets in, usually within the hour. Occasionally no headache follows. Most typical are the well-known 'fortification spectra' (teichopsia), starting near the fixation point in one half-field and expanding to the periphery as a semicircle of shimmering highly coloured zig-zag lights. Other forms consist of moving coils, curving lights or rippling sensations in the visual field. Not all are confined to one half-field of vision. A negative scotoma may follow in their wake, or constitute the whole of the aura in itself. Monocular scotoma can occur due to involvement of retinal vessels. Other disturbances include micropsia, macropsia, distortions of shape and position, 'zoom vision' and 'mosaic vision'. Occasionally there are hallucinations and distortion of taste, smell and hearing. Tactile paraesthesiae may coexist with the visual disturbances or occur alone. Problems with language may take the form of anomia or difficulty with speaking (Ardila & Sanchez 1988). Body image disturbances, though rare, can take fascinating forms, as discussed in Psychiatric features associated with attacks (later in chapter). After the attack there is often a period of resolution lasting a few hours. The person may feel tired or washed out or have difficulties concentrating. Sometimes scalp tenderness is present. Mood changes include irritability and depression, but the occasional person feels refreshed or euphoric after the attack.

A not uncommon variant, seen in about 10% of cases, is *basilar-type migraine* or *basilar artery migraine* (Bickerstaff 1961a; Kirchmann *et al.* 2006). The attacks begin with a visual aura, sometimes extending to both half-fields and obscuring vision, then proceeding to symptoms of brainstem dysfunction such as vertigo, dysarthria, ataxia, tinnitus, and sensory symptoms distally in the limbs and around the lips and tongue. Symptoms are often bilateral. After several minutes to three-quarters of an hour these give way to throbbing headache usually of occipital distribution. Loss of consciousness may be interposed between the brainstem symptoms and headache, lasting sometimes for up to half an hour and presumably due to ischaemia of the reticular formation. The impairment is gradual in onset, resembling deep sleep rather than syncope. Attacks of basilar migraine appear to be especially common in women. The episodes are usually interspersed among classic attacks.

Familial hemiplegic migraine (Thomsen *et al.* 2002) is an autosomal dominant condition characterised by attacks of transient hemiplegia that are followed by headache (Ducros *et al.* 2001). The hemiparesis is always associated with sensory, language or visual disturbances and in one-fifth of cases the attacks are accompanied by confusion or drowsiness. The aura symptoms tend to be of longer duration than in other types of migraine. In a proportion, particularly in younger patients and sometimes following a mild head injury, prolonged episodes of an encephalopathic-like illness, lasting days and weeks, may be seen (Ducros *et al.* 2001). The majority of cases have symptoms of basilar migraine, and in 20% of families patients have permanent cerebellar signs. Familial hemiplegic migraine is rare and is largely of interest in view of the genetic findings (see below), which are generally not found in sporadic hemiplegic migraine.

Other varieties of migraine include attacks in which components other than headache dominate the clinical picture (previously known as 'migraine equivalents'). The headache may be mild or even totally absent, leading to considerable diagnostic difficulty if a history of more typical attacks is not forthcoming. Thus the visual aura or other neurological disturbance may occur alone, or there may be episodes of nausea and vomiting, abdominal pain or drowsiness. Some of the mental phenomena that may constitute equivalents are discussed below. Migraine aura can occasionally mimic TIA, and some TIAs, particularly in the basilar artery territory, can be associated with headache. Slow progression of symptoms may be a helpful distinction, generally present in migraine aura and absent in TIAs.

Cluster headaches, previously called 'migrainous neuralgia', consist of severe unilateral head or face pain, usually periorbital, typically occurring in bouts over a period of several weeks and often appearing at exactly the same time each day. Attacks are accompanied by lacrimation and nasal blockage on the ipsilateral side, and sometimes by Horner's syndrome. Cluster headaches are no longer considered to be a migraine variant, and are classified by the IHS as one of the trigeminal autonomic cephalalgias. Activation of hypothalamic, rather than brainstem, blood flow is found (May *et al.* 1998).

Retinal migraine is probably at best exceedingly rare. A review of the literature of case reports of retinal migraine found that the vast majority failed to meet, for one reason or other, the IHS criteria of at least two attacks of fully reversible monocular visual symptoms followed by migraine headache (Hill *et al.* 2007). The accompanying editorial described retinal migraine as an oxymoron (Winterkorn 2007) because it is highly unlikely that the pathophysiology underlying migraine aura, involving spreading depression over the cortex (see below), could apply to the retina. 'Ophthalmoplegic migraine', with attacks of headache accompanied by paresis of external ocular movement, again often outlasting the headache, is no longer considered a migraine variant and

is classified by the IHS as a cranial neuralgia (Subcommittee IHSC 2004).

Course and outcome

Once established, migraine is commonly a lifelong complaint, although spells of relief may occur for years at a time. The frequency and severity of attacks vary greatly from one patient to another. Some are affected at fairly regular intervals, and a small number of women are especially susceptible around the time of their menstrual periods. Temporary relief during pregnancy is well attested in approximately 60% of cases. The prevalence declines beyond the age of 50 years in both men and women (Steiner *et al.* 2003). Nevertheless, in some patients headaches become more frequent over time and the illness is considered to have 'transformed' into chronic migraine, defined as headaches without aura on at least 15 days a month for at least 6 months. Precipitating factors, for example fatigue or sleep, stress, particular foods or drinks, menstruation, weather (Prince *et al.* 2004) and infections, are probably not particular to migraine headache, being almost as common before episodes of non-migraine headache (Chabriat *et al.* 1999).

Migraine is associated with strokes. Dorfman *et al.* (1979) demonstrated infarctions by angiography or CT in four young adults with migraine, one representing a posterior cerebral artery occlusion and three infarctions in the middle cerebral territory. However, Broderick and Swanson (1987) were able to find only 20 examples of stroke occurring with an attack among almost 5000 patients at the Mayo Clinic. Good recovery was usual, only two being left with moderate disability and 14 with mild or minimal disability. Bogouslavski *et al.* (1988) made a careful comparison between 22 patients who suffered a stroke during an attack and matched migraine patients who had suffered strokes remote from attacks. A second control group consisted of non-migraineurs with stroke. Those with stroke during an attack were less likely to have cardiovascular abnormalities as potential sources of emboli, and more likely to have a prolonged duration of attack. Such features suggested that strokes which occur during the course of attacks were intimately related to the pathophysiology of the migraine process, i.e. probably attributable to prolonged oligoemia in the territory responsible for the auras. The conclusion from a review of the relation between stroke and migraine is that the risk of suffering ischaemic stroke is increased in patients with migraine, particularly in young women (Boussier & Welch 2005). However, the absolute risk is nevertheless very low, i.e. the vast majority of young patients with migraine with aura will not suffer a stroke.

Findings of possible relevance have come from brain imaging. Hungerford *et al.* (1976) found evidence of infarction in 6 of 53 patients with very severe migraine, three of the infarctions corresponding in site to aspects of the clinical

history. Of the 13 patients with permanent neurological sequelae, 11 showed some abnormality on the scan. MRI has also revealed abnormalities, chiefly scattered areas of high T2 signal intensity in the subcortical white matter, sometimes with larger cortical changes resembling infarcts. In a meta-analysis of seven studies, white matter abnormalities were found to be almost four times as common in migraine patients as controls (Swartz & Kern 2004); the increased risk was seen even in those studies restricted to patients less than 55 years old. One large study of subclinical brain lesions found that the risk of deep white matter abnormalities, as opposed to periventricular abnormalities, was raised by migraine, particularly in those with aura and frequent attacks and particularly in women (Kruit *et al.* 2004). In those with extensive periventricular lesions or large lacunar infarcts in deep white matter, it is important to rule out other conditions, including CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy) and small-vessel disease. Small silent infarcts are found in about 10% of migraine, almost all in the posterior circulation particularly involving cerebellum (Kruit *et al.* 2005).

The mechanism underlying the increased risk of ischaemic stroke in migraine is unknown. Migrainous infarcts, i.e. infarcts during a migraine attack, only account for a small proportion of the risk at most; most ischaemic strokes in patients with migraine occur between migraine attacks (Boussier & Welch 2005). It may be the case that ischaemia-induced migraine is more common than migraine-induced ischaemia (Olesen *et al.* 1993); in a significant proportion of cases with both migraine and cerebral infarct, a definite cause for the infarct (e.g. cardioembolic source or carotid stenosis) was found. Various vascular disorders, including patent foramen ovale (Domitrz *et al.* 2007), mitral valve prolapse, thrombocythaemia and systemic lupus erythematosus, may be associated with increased rates of migraine, in addition to their increased risk of stroke. Finally, it must be remembered that MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis and stroke), CADASIL (Gladstone & Dodick 2005) and a condition of autosomal dominant vascular retinopathy, migraine and Raynaud's phenomenon are three rare conditions that may produce both ischaemic stroke and migraine with aura (Boussier & Welch 2005).

Epilepsy and migraine occur together more frequently in the same person than would be predicted by a chance association. About 6% of patients with migraine have epilepsy, much higher than the rate in the general population (Haut *et al.* 2006). Furthermore, in a study of 1948 patients with epilepsy and 1411 of their parents and siblings, 24% of those with epilepsy had migraine compared with 12% of relatives without epilepsy. There was no convincing relationship between type of epilepsy and risk of migraine (Ottman & Lipton 1994). Both epilepsy and migraine may be related to the menstrual cycle, and the same drugs may be effective in both conditions. It has been suggested that both may be dis-

orders of neuronal hyperexcitability (Aurora *et al.* 1999; Haut *et al.* 2006); two studies have found that migraineurs are more likely to experience phosphenes during transcranial magnetic stimulation of the occipital cortex, though one study has failed to replicate this.

Pathophysiology

The hypothesis that migraine should be understood as a disorder of neuronal hyperexcitability has gained support from the finding that many patients with familial hemiplegic migraine have genetic mutations. In all cases these mutations involve polymorphisms of genes regulating ion translocation. The first to be identified was a mutation in the gene, on chromosome 19, for the voltage-gated calcium channel (Ducros *et al.* 2001). Since then families have been found where the mutation is either in the gene coding for the Na⁺/K⁺ pump or in the gene for the neuronal voltage-gated sodium channel. It has been suggested that in each case, whether the abnormality is in the voltage-gated calcium or sodium channel or the Na⁺/K⁺ pump, the final common pathway to the migraine aura is excessive potassium or glutamate release which facilitates cortical spreading depression (see below) (Sanchez-Del-Rio *et al.* 2006). However, these changes in ionic regulation may also affect neuronal activity in brainstem nuclei (see below).

Previous hypotheses suggesting that migraine aura was caused by vasoconstriction, with the headache produced by the subsequent vasodilation, have now been discarded. Instead, migraine is now conceived as being related to events in the cortex and adjacent meninges on the one hand and in the brainstem on the other. These events are linked by sensory fibres of the trigeminal nerve conveying signals from meningeal nociceptors to the brainstem, and efferent fibres of the parasympathetic system controlling meningeal blood vessels, this afferent and efferent loop being part of the trigeminovascular system (Pietrobon & Striessnig 2003). The events of interest comprise:

- cortical spreading depression over the cerebral cortex, which is relevant to the aura of migraine but perhaps not to migraine without aura;
- effects of neuropeptides and other neurotransmitters, particularly 5-hydroxytryptamine (5HT), on meningeal vasculature and nociceptors;
- altered function of aminergic brainstem nuclei and their parasympathetic outflow.

Cortical spreading depression, a wave of neuronal and glial depolarisation with reduced neuronal activity and reduced blood flow that spreads across the cortex at a rate of about 2–3 mm/min, is very probably the cause of migraine aura (Sanchez-Del-Rio *et al.* 2006). In animals, spreading depression can be triggered by local application of high concentration of potassium, which then causes a wave of depolarisation to spread outwards. The extracellular con-

centrations of potassium, nitric oxide and glutamate are raised. In patients with migraine aura the studies of Lauritzen (1994) and colleagues have shown a wave of oligoemia travelling across the cortex, usually starting posteriorly and spreading anteriorly over the course of 15–45 minutes to involve parietal and temporal regions. The spread of oligoemia is independent of the territories supplied by the larger cerebral vessels, but like cortical spreading depression may fail to cross prominent cortical sulci (e.g. parieto-occipital sulcus) (Hadjikhani *et al.* 2001). The reduction in blood flow, of the order of 20–30%, is coupled to the reduced metabolic demand (Olesen *et al.* 1981; Lauritzen 1994), an observation which tallies with the absence of ischaemic change on diffusion-weighted MRI (Cutrer *et al.* 1998). A short phase of hyperaemia on the leading edge of the oligoemia may be responsible for the flashing jagged lights of the visual aura; using fMRI in three patients with visual aura it was possible to link the increase in BOLD signal, indicating greater blood oxygenation, to the patient's experience of scintillations moving across the visual field (Hadjikhani *et al.* 2001). Nitric oxide and inflammatory cytokines released from cortex affected by spreading depression may sensitise overlying meninges and trigger the migraine headache.

Activation of nociceptors in the meninges and meningeal vessels is responsible for the headache of migraine, whether or not preceded by aura. Neuropeptides, especially calcitonin gene-related peptide (CGRP), released by nerve terminals of the trigeminal sensory nerves act as vasodilators and contribute to what is effectively an inflammatory response with plasma extravasation and mast cell degranulation in the dura (neurogenic inflammation). 5HT is also involved because ergotamine and triptans both work by blocking 5HT receptors at various levels of the pathway, including those on meningeal blood vessels and trigeminal nerve endings. Sensitisation of the trigeminal nerve and its sensory nuclei explains why a proportion of patients complain of cutaneous allodynia in the trigeminal distribution (Burstein *et al.* 2000). The trigeminal nerve carries the sensory nociceptive signals to the brainstem.

In the rostral brainstem (dorsolateral pons), increased blood flow on PET is found during acute migraine headache (Bahra *et al.* 2001) and in those with chronic migraine (Matharu *et al.* 2004). In those with unilateral headache this effect is lateralised, although one group studying nine patients all with right-sided headache found contralateral brainstem activation (Weiller *et al.* 1995), whereas another group studying glyceryl trinitrate-triggered attacks found ipsilateral brainstem activation (Afridi *et al.* 2005). The activation continues after the headache is controlled by sumatriptan, suggesting that it is not simply a response to painful stimuli coming from the meninges and other intracranial vessels but may play an active role in the pathogenesis of the headache. The lateralised nature of the activation may explain why the headache is lateralised in many patients.

These findings are consistent with the hypothesis that migraine headache (Goadsby 2006) is explained by abnormal behaviour of aminergic brainstem nuclei that take part in the trigeminovascular loop (Pietrobon & Striessnig 2003). These nuclei, which include the trigeminal nucleus pars caudalis on the afferent side and the superior salivary nucleus on the efferent side, modulate sensory input from the meninges and, via their parasympathetic afferents, influence cranial vasculature. The consequent vasodilation enhances the inflammatory response described above.

The site of the changes responsible for auras must differ widely from one form to another. Teichopsia and homonymous field defects almost certainly originate in the occipital lobes, illusions of altered size, shape and position in the optic radiations, and bitemporal hemianopias from disturbance of chiasmatic vessels. The middle cerebral or internal carotids are likely to be involved in hemiplegic migraine, and the vertebrobasilar system in patients with brainstem manifestations. In fact it is probable that in many attacks a large part of the cerebral vasculature is affected diffusely, the focal symptoms merely reflecting ischaemia in the territory most severely involved, hence the vague but definite symptoms of slowed cerebration and somnolence common in attacks.

In the case of prolonged neurological phenomena, as in hemiplegic migraine, local oedema or hypoxia consequent on the spasm may be responsible for the symptoms.

Psychiatric aspects

Virtually all observers, neurologists and psychiatrists alike, stress the influence that psychological factors may have in migraine and the importance attaching to them in treatment. A considerable literature has accumulated concerning the personality of migraine sufferers and the role of emotions and conflicts in precipitating attacks. Early reports suggested that it was possible to identify a personality type that was particularly prone to suffering migraine. However, the anecdotal observations on which such conclusions were based are vulnerable, not least to ascertainment effects. It has for example been shown that personality type may predict who attends clinic for help rather than who in fact has headache (see below). With more rigorous methods, avoiding ascertainment bias and using reliable measures of personality and other psychopathology, the story is found to be a little more complicated. Mental phenomena are also recognised as common accompaniments of the migraine ictus, and may sometimes assume bizarre expression leading to diagnostic difficulty. These aspects are briefly reviewed.

Anxiety and depression

Patients with migraine are at increased risk of anxiety and depression. Population surveys consistently show that the risk of a person with migraine suffering depression or anxiety is at least twofold to threefold that of somebody without

headache (Table 8.1). For example, a study of 1007 adults in Detroit found a lifetime prevalence of migraine of 12.8% and a 1-year prevalence of 9.2% (Breslau *et al.* 1991). Approximately half had migraine with aura; 26.5% of migraineurs had major depression compared with 9% of the non-migraine subjects, giving an odds ratio (OR) of about 3. The rates of any anxiety disorder were 53% and 27% respectively (OR 2.6).

In a prospective study of a cohort of 27- and 28-year-olds in Zurich, 61 of the 457 subjects were deemed to suffer from migraine, and these showed a significant excess of major depression, bipolar spectrum disorder (i.e. cyclothymia and hypomania), generalised anxiety and social phobia (Merikangas *et al.* 1990). For example, 14.7% of the migraineurs compared with 7.3% of controls had major depression (OR 2.2). The association with anxiety disorders was particularly strong, the corresponding figures being 31.2% versus 14.1% (OR 2.7). Retrospective data suggested a characteristic time course, with anxiety often manifested in childhood, followed by the development of migraine some years later, and then by discrete episodes of depression in early adult life. Similar figures were found by Swartz *et al.* (2000); of 1729 adults, those with migraine compared with controls had elevated risks for major depression (OR 2.2), panic disorder (OR 3.4) and phobias (OR 1.4). In a combined USA/UK study of over 300 adults with migraine and 300 controls, using PRIME-MD (Primary Care Evaluation of Mental Disorders) to identify depression, 47% of migraineurs compared with 17% of controls were depressed (Lipton *et al.* 2000). There were independent contributions of depression and of migraine to the Reduction in quality of life seen in the patients with migraine.

In general these studies (Table 8.1) find that the increased risk of having an anxiety disorder is greater than that for having depression. In those studies that have looked at the overlap, many cases are found to have mixed anxiety and depression. The risk of suicide attempt is also increased in migraine, and it is of interest that not all this excess risk is explained by the presence of depression (Breslau 1992).

It is a mathematical necessity that when people in a cohort must belong to only one of four categories (i.e. both depressed and suffering migraine, depressed but not suffering migraine, suffering migraine but not depressed, neither depressed nor suffering migraine), then the OR for depression if you suffer migraine is the same as the OR for migraine if you suffer depression. Therefore these studies also tell us that those who are depressed, and those with anxiety disorders, are at increased risk of suffering migraine. Thus in studies of patients presenting with major depression (Hung *et al.* 2005; Oedegaard & Fasmer 2005), about half are found to have migraine.

Various studies have looked at the specificity of the effect. Is the excess risk of emotional disorder restricted to migraine headache, or is it also seen in non-migraine headache? For those with migraine is the risk greater for those with or

Table 8.1 Rates and odds ratio (OR) for anxiety and depression in people with migraine and people without headache defined in population-based surveys.

without aura? The first study to examine this found that patients with migraine were more likely to be depressed than patients with tension-type headache, but did not check that this was not simply related to greater severity of headaches (Merikangas *et al.* 1994). A subsequent study comparing 536 people with migraine with 162 with severe headache and 586 controls found no significant difference between rates of depression in migraine and non-migraine headache, although there was a trend for the former to suffer worse depression (Breslau *et al.* 2000). Lifetime prevalence of major depression was 40.7% in migraine, 35.8% in severe non-migraine headache and 16% in controls, giving adjusted ORs

of 3.5 and 3.2 respectively. If anything, migraine patients with aura were more likely to suffer depression than patients with migraine without aura, the rates of major depression being 49% (OR 4.9) and 37% (OR 3.0) respectively.

A similar picture emerges from Norway based on a population survey of over 90 000 residents aged over 20 years. From this survey full questionnaire returns were available for 49 000, allowing the presence of migraine or other headache to be compared with the presence of anxiety and depression, the latter measured using HADS. Although the study had the advantage of being large, it relied on questionnaire assessment for the diagnosis of migraine with aura, migraine

without aura, and other headache. This probably had the effect of making the study less powerful at detecting any differences between these three conditions because of cross-contamination across the three cohorts. In other words, because of misclassification some of the migraine with aura cohort will contain patients with migraine without aura, and so on. Nevertheless, a previous study had shown that the questionnaire methods had reasonable reliability compared with interview diagnoses. It was also reassuring that their figure of 12% with migraine headache within the previous 12 months is consistent with other prevalence studies; more than twice as many, 26%, had non-migraine headache. In the first paper (Zwart *et al.* 2003), rates of anxiety and depression were compared in those with migraine headache, non-migraine headache and controls. The risk of both depression and anxiety was increased in both migraine and non-migraine headache, with ORs between 2 and 3. The risk was slightly, but not significantly, higher in migraine, and was higher for anxiety than for depression in both types of headache. In both cases, i.e. regardless of headache type, there was a strong dose-response relationship: those with more frequent headache were more likely to be depressed. The second paper (Oedegaard *et al.* 2006) considered whether those with migraine with aura were more at risk of anxiety and depression than patients with migraine without aura. No significant difference was found between these two groups, although there was a trend for migraine with aura to have higher rates of anxiety and depression, and this was significant for the risk of depression in women with aura.

Therefore patients with migraine are not very different from patients with non-migraine headache in terms of their vulnerability to emotional disorders, although if anything the risk is greatest in those with migraine with aura and least in those with non-migraine headache. In fact the risk of depression and anxiety in migraine may not be very different from that found in arthritis or back pain (McWilliams *et al.* 2004). This suggests that it is the pain of migraine headache that results in depression and anxiety. However, one longitudinal study of the relation between depression and migraine suggests that depression may increase a person's vulnerability to migraine. At baseline both migraineurs and non-migraine headache sufferers had similar rates of lifetime major depression (42% vs. 36%) (Breslau *et al.* 2003). The authors then looked at those people who did not have headache at baseline to find out if they developed a first migraine attack over the 2-year follow-up. Being depressed at baseline markedly increased the risk of developing migraine compared with not being depressed (OR 3). This effect was specific for new-onset migraine headache; being depressed did not raise the risk of developing non-migraine headache over the next 2 years. The study did not report antidepressant usage, so it is possible that being on an antidepressant, rather than being depressed, was causing the increased risk of migraine. However, another study found the presence of

phobia, not depression, to predict who would develop migraine. In this study participants were identified by community sampling in 1981 and followed up 12–15 years later (Swartz *et al.* 2000). Full psychiatric assessments were made at both time points. A total of 1343 patients who had not been suffering headaches in 1981 were followed up; of these, 118 (8.8%) had developed migraine (incident migraine). Those with an affective disorder in 1981 were not at greater risk of developing migraine, neither was there any effect of antidepressant usage. Only a phobia diagnosis in 1981 was associated with increased risk of developing migraine (OR 1.7).

Personality and stress in migraine

Many accounts stress the driving conscientious personality of migraine sufferers, often with marked obsessional traits and above-average intelligence. Such a picture originated with the work of Wolff (1937, 1963). Wolff's migraineurs were described as overtly obedient but with traits of stubbornness and inflexibility. Most were ambitious and preoccupied with achievement and success, attempted to dominate their environments, and were exacting and meticulous. Many harboured strong resentments that were linked to their intolerance and superabundance of drive. Sexual dissatisfaction was common. Such features, when present, appeared to furnish optimal conditions for the precipitation of attacks. Psychoanalysts have highlighted certain other constellations in the personality, for example repressed hostility and unresolved ambivalence resulting in compulsive behaviour and rigidity (Fromm-Reichmann 1937; Spurling 1964) or the role of sexual conflicts.

However, it is unlikely that generalisations can be made about the personality make-up of migraine patients. Sacks (1970) illustrated the variety of emotional needs that attacks appeared to fulfil, and found it impossible to fit his material into stereotypes of obsessive personality or chronically repressed hostility. Selby and Lance (1960) made a rough categorisation of their patients and considered that the personality range differed little from what occurs in the population generally: 23% showed obsessional trends, 22% were hyperactive and found it hard to relax, 13% showed overt anxiety symptoms and 42% were considered 'normal'. However, these studies used somewhat idiosyncratic methods of personality assessment. It is possible that more sensitive and better-validated methods of personality assessment might yield positive results.

Studies using standard measure of personality, for example the Minnesota Multiphasic Personality Inventory (MMPI) or Cloninger's seven-factor Temperament and Character Inventory (TCI), do find evidence of increased rates of neuroticism, or traits consistent with neuroticism such as harm avoidance or social introversion. In China a study of 80 patients with migraine found them to have elevated scores on the paranoia and social introversion scales of the MMPI compared with non-headache controls (Fan & Zhou 1999).

Elevated scores on hysteria and hypochondriasis improved with treatment of the migraine (Fan *et al.* 1999). Nylander *et al.* (1996) found that 26 migraine patients from a large Swedish family were no different from controls on the TCI, except that the subjects with migraine had slightly higher scores on novelty seeking (i.e. less likely to seek novelty); the authors suggested this was because they had high levels of somatic anxiety symptoms. Another study using the TCI obtained a slightly different result; patients with migraine without aura had higher scores than controls on problems with anger management and harm avoidance (Abbate-Daga *et al.* 2007). Psychasthenia and social introversion may be higher in those with chronic as opposed to episodic migraine (Karakurum *et al.* 2004). Comparing migraine with or without aura, only the migraine without aura group were found to have increased scores on a measure of aggression–hostility judged against healthy controls; no abnormal personality traits were found in migraine with aura patients (Cao *et al.* 2002). Patients who responded to sumatriptan have been compared to those who did not respond (Meckling *et al.* 2001); the former, if women, had headache that was more influenced by menstrual factors, whereas the non-responders had higher rates of anxiety and neuroticism.

However, increased rates of neuroticism may not be specific for migraine headache; studies have found elevated scores on measures of anxiety, neuroticism and harm avoidance that are equivalent in patients with migraine and those with tension-type headache (Di Piero *et al.* 2001; Cao *et al.* 2002; Mongini *et al.* 2005). Indeed, in one study only tension-type headache, not migraine, was associated with high neuroticism scores on the Eysenck Personality Inventory (EPI) (Rasmussen 1992). These observations are in line with a study that examined the effect of undertaking a mental arithmetic task as a mental stressor in patients with migraine or tension-type headache; in both headache groups symptoms of fatigue took longer to recover compared with controls (Stronks *et al.* 1999).

The studies that have just been described were by and large performed on clinic populations, with the danger that special selection may have been at work. Waters' (1971) survey of a community-based sample is informative. No evidence was found to support the contention that migraine is especially common among persons of higher intelligence, although it was noted that a higher proportion of the more intelligent sufferers had consulted doctors about their headaches. Similarly, there was no indication that migraine was especially frequent among persons in social classes I and II, a finding that has been replicated (Rasmussen 1992). However, Waters did find a tendency for a higher proportion of migraineurs in social classes I and II to have consulted their doctors. More recently, the characteristics of headache sufferers who sought medical advice and treatment over the previous 2 years was compared with those, with approximately the

same headache severity, who did not (Ziegler & Paolo 1995). The proportion of migraine sufferers in each group was about the same but the clinic attenders had higher rates of psychasthenia, hysteria, hypochondriasis, social introversion and depression. This selection bias might well explain some of the findings described in the previous paragraphs.

Henryk-Gutt and Rees (1973) surveyed a large population of government employees and matched the migraine sufferers with carefully chosen controls, thus overcoming the selective processes involved in medical referral. Semi-structured interviews and personality inventories were used to explore psychological aspects of the disorder. They obtained no evidence of increased ambitiousness, striving or obsessiveness among the migraine subjects, nor was there any relation to hostility and guilt. However, 'neuroticism', as measured by the EPI, was significantly higher than among controls, likewise indices of emotionality as manifest in current nervous symptoms, current emotional difficulties, liability to mood swings and tendencies to bottle up anger and resentments. Another study based on a community sample also found elevated scores on the neuroticism scale of the EPI, but this time only in women (Breslau *et al.* 1996). However, in a study of 728 women aged between 40 and 72 years attending a population-based mammography screening service, overall there was no association between lifetime migraine headache and personality traits (Mattsson & Ekselius 2002).

Therefore the evidence that a particular personality type predisposes a person to suffering migraine is not very strong. Nevertheless, it seems quite likely that people with migraine do have higher scores on neuroticism traits, including harm avoidance, psychasthenia and social introversion, particularly if they attend a migraine clinic. Migraine subjects may therefore be constitutionally predisposed towards increased emotional reactivity, and this increased reactivity of the autonomic nervous system could conceivably provide the predisposing factor for the development of attacks. Such factors probably also increase the risk of being treatment unresponsive and developing chronic migraine. However, such character traits are not very specific for migraine headache, and may be common to all patients with headache. Furthermore, there seems no evidence that patients with migraine with aura are at particularly high risk of increased neuroticism, indeed the opposite.

Psychological precipitants

Many observers place psychological factors high on the list of features that may provoke episodes of migraine. It is common to find that periods of stress, or the anticipation of stress, are associated with attacks. Sustained emotional tension seems to be more important than acute emotional disturbance, the crucial factor being the degree to which feelings are sustained, bottled up and inadequately expressed (Rees 1971). Frustrations and resentments may

operate powerfully in this way. Another well-documented finding is the tendency for some patients to develop attacks during the 'let down period' after intense activity and striving. Consequently, some have attacks quite regularly when a harassing day is over, at weekends or on the first day of a holiday. However, many patients insist that the majority of their attacks are entirely without discernible precipitants. Emotional disturbance therefore appears to be a common but by no means universal factor. Migraine subjects attending a headache clinic report higher levels of stress on the Perceived Stress Questionnaire than do controls (Wacogne *et al.* 2003), including more 'intrusive thoughts about work' and 'feeling under pressure'.

Some two-thirds of clinic-based samples report that emotional precipitants are important, though rarely as the sole invariant factor (Selby & Lance 1960; Dalsgaard-Nielsen 1965). In their community survey, Henryk-Gutt and Rees (1973) found about 60% in whom problems at work or problems with interpersonal relationships were regarded as direct precipitants. Relief from strain was noted as a factor in about one-third. In controls with non-migrainous headaches such features were less commonly blamed. In almost half of the migraine subjects the disorder had had its onset during a period of emotional stress. The subjects were then asked to keep records of their attacks for a 2-month period, noting any special events or emotions coinciding with the attacks. Over half of the episodes recorded proved to be related to emotionally stressful events. Other precipitants such as alcohol, food or hunger were by comparison very rare. In approximately one-third of attacks no cause whatever could be discerned. A more recent study used very similar methods in 20 women with migraine, again over a 2-month period (Holm *et al.* 1997); 14 (70%) showed at least some relation between the amount of stress they experienced and their headache, and in four women there was a strong correlation between daily stress and headache severity. From a review of three previous studies, not including that of Henryk-Gutt and Rees (1973), the authors confirmed that on average about half of migraine subjects showed an effect of stress on likelihood of migraine headache. In general the effect was seen on the day of the stressor, but in one study stress preceded migraine headache by 1–3 days.

Psychiatric features associated with attacks

As noted above, feelings of irritability and anxiety may last for several hours as a prelude to attacks. More rarely patients may experience unusual health and vigour, sometimes amounting to elation. A rebound of energy is also described in the wake of attacks, with feelings of buoyancy and increased drive. Others by contrast remain listless and fatigued for several days. Such features may sometimes occur with sufficient regularity to suggest that they are an essential part of the pathophysiology of the disorder.

Mental changes are almost universal during the attack itself. Anxiety and irritability are common early on, with drowsiness and lethargy as the headache continues. Depression can be severe. Cerebration is typically slowed, with poor concentration and poor ability to think coherently. Klee (1968) made a detailed analysis of patients with migraine severe enough to warrant hospitalisation, and found that attacks were accompanied by marked impairment of memory in 10%, clouding of consciousness or delirium in 8%, pronounced anxiety in 8%, complex visual and auditory hallucinations in 6%, changes of body image in 6% and severe depression in 4%. Altogether 22% of patients experienced at least one mental symptom severely enough to affect them greatly in the course of their attacks.

Alterations of consciousness range from blunting of alertness, through states of marked lethargy and drowsiness to frank loss of consciousness. The latter is the so-called 'migrainous syncope', sometimes occurring during the aura and sometimes later in the attack. Typically the patient lapses into unconsciousness over a period of several minutes, appears as though sleeping deeply, then emerges from the episode in the same gradual fashion. Such attacks have been described as characteristic of basilar artery migraine (Bickerstaff 1961b) but can also be seen with hemiplegic migraine and other varieties. On rare occasions there may be short-lived periods of coma with incontinence or even epileptic fits at the height of attacks.

Mental 'confusion' can be marked. Sometimes it represents a focal disturbance of cerebral function with dysphasic, apraxic or agnosic manifestations. Disturbance of memory can be the main component, as described below by Sacks (1970), or there may be elaborate 'dreamy states', probably reflecting temporal lobe dysfunction, with feelings of *déjà vu*, timelessness, depersonalisation or forced reminiscence.

A 44-year-old man suffered very occasional attacks of migraine from adolescence, ushered in by scintillation scotomata. In one attack a profound dream-like state followed the visual phenomena.

First I couldn't think where I was, and then I suddenly realised that I was back in California . . . It was a hot summer day. I saw my wife moving about on the verandah, and I called her to bring me a Coke. She turned to me with an odd look on her face, and said 'Are you sick or something?' I suddenly seemed to wake up, and realised that it was a winter's day in New York, and there was no verandah and that it wasn't my wife but my secretary who was standing in the office looking strangely at me.

Other examples clearly represent acute organic reactions due to generalised cerebral dysfunction, with disorientation and clouding of consciousness. Medicaments administered for treatment of the attack may sometimes be partly responsible. Such states may be coloured by anxiety, restlessness and complex visual and auditory hallucinations. A paranoid element may be marked. The condition may amount to a frank delirium, lasting throughout the headache for several hours or days. Very occasionally the headache fails to materialise and the mental disturbance then appears as a psychotic episode in itself ('mental migraine equivalent'). Psychosis is very rare as a fully developed manifestation, and is usually seen as an elaboration of an acute organic reaction.

A 37-year-old housewife had suffered attacks of migraine from 19, increasing in severity since the age of 32. Attacks began with headache, later proceeding to paraesthesiae in the right hand and leg with weakness of the limbs and a variety of visual phenomena. They often lasted for 3 or 4 days. During a particularly severe attack which lasted for a week she had to be admitted to a mental hospital. On the preceding day she had become increasingly restless with clouding of consciousness, had heard neighbours making unpleasant comments about her and believed she had been stuck with knives. For the first few days in hospital she was disorientated, restless and appeared hallucinated both visually and aurally. She heard children's voices and the voice of her general practitioner, and believed her legs had been amputated. This psychotic episode disappeared within a few days and she was amnesic for it afterwards. Her last clear memory was of lying down to sleep at home, and the next of waking in hospital (Klee 1968).

However, Bhatia (1990) has described a patient with Capgras syndrome, setting in during the headache despite normal orientation and memory and persisting for several weeks. Fuller *et al.* (1993) described a case in which psychotic features were in the forefront of the picture, four episodes occurring over a 17-year period and each setting in within 24 hours of migraine attacks, and only one being associated with disorientation.

Hallucinatory elements may sometimes dominate the picture, as in one of Klee's (1968) patients who saw greyish-coloured Red Indians, 20 cm high, crowding round in the room in which he lay. On another occasion he picked up hallucinatory musical instruments from the floor. Another patient saw 'white living creatures', stationary and rather indistinct, apparently unaccompanied by clouding of consciousness or disorientation.

Florid examples of confusion are probably rare, at least in adults. However, in children it seems not uncommon for migraine to present in this fashion. Gascon and Barlow (1970) observed four children who showed acute organic reactions lasting from 6 to 24 hours. Although headache developed in every case it was usually not detected until the mental disturbance had receded. Ehyai and Fenichel (1978) found five similar examples among 100 consecutive cases of childhood migraine, with episodes of agitated confusion lasting from several minutes to hours, and succeeded by diffuse EEG changes indicative of cerebral ischaemia. Such attacks tended to recur on follow-up but were eventually replaced by typical migraine.

Amnesia may feature prominently in some episodes, either alongside the visual aura or as a variant of classic attacks.

A 37-year-old doctor complained of episodes of mental disturbance lasting 3–6 hours at a time, and occurring once or twice per year from the age of 18. They began with a feeling of mild depression, then strangeness, then mental confusion. Throughout the attack he remained perfectly orientated, yet was unable to organise his thinking and had large defects in his memory. Facts and events seemed isolated and devoid of normal associations. He was unable to remember things for more than half a minute and found it difficult to converse as a result, repeating questions and appearing absent-minded to onlookers. Close questioning revealed migraine attacks with scotomata and fortification spectra occurring between such episodes. The more typical attacks were also associated with very mild confusion (Nielsen 1930).

Caplan *et al.* (1981) have reported an association between the syndrome of transient global amnesia and migraine, describing 12 migraineurs who experienced a typical amnesic episode. Six were cases of common migraine and six of classic migraine. Of the latter, three experienced their classic aura accompanying the attack and headache followed it; two more had pounding headache during the attack. Altogether 9 of 12 experienced headache in the course of the amnesic episode. Pathophysiological mechanisms similar to those of migraine may be present in a substantial proportion of patients with transient global amnesia.

Body image disturbances may occur just before, during or after attacks of headache. Parts of the body are felt to be magnified, diminished, distorted, reduplicated or absent. Lippman (1952) reported several examples, all in classic migraine, including patients in whom the abnormal sensations could

constitute the entire attack without headache developing. One patient felt as though the neck or hip were extending out on one side, another that the left ear was ballooning out for 15 cm or more, another that the head had grown to tremendous proportions and had become light, floating up to the ceiling. One patient felt alternating enlargements and diminutions in the size of the right half of the body, coming and going throughout the headache period. Patients who feel exceedingly tall or extremely minute during attacks are suggestive of *Alice in Wonderland* and Lewis Carroll was known to have suffered from migraine.

Lippman (1952) also described experiences of physical duality associated with migraine. During attacks such patients felt a conviction of having two bodies, usually for several seconds at a time, before, during or after the headache. Qualities such as observation, judgement and perception were typically transferred to the 'other' body which for the moment seemed the more real of the two, but throughout the experience the patient remained aware of the actual body and its position in space. Feelings of fear, mild wonder or amazement were common accompaniments. This striking phenomenon is best illustrated by one of Lippman's (1952) examples.

A woman of 37 wrote:

'Until . . . 5 years ago, I felt the queer sensation of being two persons. This sensation came just before a violent headache attack and at no other time. Very often it came as I was serving breakfast. There would be my husband and children, just as usual, and in a flash they didn't seem to be quite the same. They were my husband and children all right – but they certainly weren't the same . . . There was something queer about it all. I felt as if I were standing on an inclined plane, looking down on them from a height of a few feet watching myself serve breakfast. It was as if I were in another dimension, looking at myself and them. I was not afraid, just amazed. I always knew that I was really with them. Yet there was 'I' and there was 'me' – and in a moment I was one again!

Cognitive impairment and migraine

Progressive mental impairment has occasionally been noted in sufferers from severe migraine, although a causal connection has not been clearly established and any association would certainly appear to be rare. Symonds (1951) considered it probable that in some cases there might be slight but cumulative brain damage as a result of successive small infarctions and this is consistent with the observation that MRI studies find an increased risk of small infarcts in the white matter. An example is reported by Bradshaw and Parsons (1965):

A 39-year-old nursing sister had suffered migraine from the age of 7, increasing after a period of worry some years before. After injecting herself with ergotamine tartrate during one attack she developed a right hemiplegic episode with dysphasia. This improved slowly over 5 weeks but left a slight residual deficit. Angiography and other investigations showed no abnormalities. Follow-up showed unequivocal evidence of progressive impairment of mental faculties, leading to memory impairment, falling standards of work, lack of insight and emotional instability. Further migraine attacks had continued, some with right-sided paraesthesiae. Her mother had suffered right hemiplegic migraine, and from the age of 52 had shown mental changes that progressed to gross dementia over the course of several years.

Pedersen (1980) has described three patients with cortical atrophy and marked signs of reduced intellect. No other causes could be found to account for this, and two of the patients had shown a marked increase in frequency of attacks prior to the onset of the dementia.

With regard to psychometry, Klee and Willanger (1966) found evidence of slight impairment in six of eight patients, and Zeitlin and Oddy (1984) reported impairments in comparison to a carefully matched control group. In the latter study, 19 patients with histories of migraine extending over 10 years were matched to controls in terms of age, sex, social class, verbal IQ and education. All were under 50 with a mean age of 36 years. Significant impairments were revealed on choice reaction time tests, Trail Making Test and Paced Auditory Serial Addition Test (PASAT), and on recognition memory for words. However, no associations emerged with measures of the severity of migraine or the use of ergotamine. A review of 12 studies of interictal neuropsychological testing in adult migraineurs found surprisingly little evidence of neuropsychological impairment (O'Bryant *et al.* 2005); the evidence suggested 'some subtle but possibly significant changes in cognition'. Psychomotor slowing was the commonest finding. Indeed, migraine with aura patients had more evidence of impairments. However, there was no evidence that migraine results in greater cognitive decline with ageing (and see also Kalaydjian *et al.* 2007) or is a risk factor for Alzheimer's disease.

Chronic migraine or transformed migraine

Occasional sufferers from migraine may enter a phase in which very frequent, severe and unremitting headaches develop. Typically this is coupled with malaise, anorexia, sleeplessness and loss of weight. Depression of considerable severity is usually an integral part of the picture. Over-medication may prove to be partly responsible, but in many cases psychological influences are clearly at work in initiating or perpetuating the disorder.

The deterioration may be decisively linked to the development of a depressive illness, the migraine and the affective disorder thereafter reinforcing each other. In other patients it may be difficult to discern which components have been primary in initiating the vicious circle once the condition has become entrenched. *Transformed migraine* is the term now used to describe the situation when headache occurs on at least 15 days of the month for on average, if untreated, more than 4 hours a day.

Differential diagnosis

Migraine headaches must first be differentiated from other causes of pain in the head and face: chronic sinus disease, glaucoma, hypertension and raised intracranial pressure. In the majority of cases the history will be sufficient to allow such a distinction, aided by physical examination or simple investigations. More difficulty may be encountered in making a firm distinction between migraine and tension headaches, both of which are common, chronic and frequently incapacitating.

Problems with neurological diagnosis are likely to arise in cases of 'complicated migraine', where marked neurological deficits accompany or follow attacks. Here a neurological opinion is essential, even though a basis in structural cerebral pathology will emerge in only a minute proportion of cases. An angioma must be considered when the deficits well outlast the headache, and especially when attacks of hemiplegic migraine involve one side of the body exclusively. Ophthalmoplegic attacks limited to one side will raise the possibility of an aneurysm of the internal carotid or posterior communicating arteries. In basilar migraine the prominence of brainstem deficits may suggest the possibility of some brainstem lesion. And even classic migraine attacks may warrant investigation if they first declare themselves in adult life, particularly if the auras tend to occur alone without much by way of headache.

Occasionally, difficulty can arise in distinguishing migraine from epilepsy, and indeed the two may occur together. When loss of consciousness occurs with migraine it is usually gradual in onset and a good deal less profound than in epilepsy. Even when sudden, it is usually succeeded by headache far exceeding that which follows an epileptic attack. Doubt can also arise over the complex auras of migraine, especially when these occur as isolated events. However, visual phenomena are far commoner in migraine than in epilepsy and often assume their highly specific form. Paraesthesiae are rarely bilateral in epilepsy, and proceed with much greater rapidity than in migraine.

Patients presenting with episodes of confusion may be suspected of delirium due to toxic or metabolic factors. Long-lasting acute organic reactions may be diagnosed as transient paranoid reactions. Episodes coloured by marked mood disturbance may resemble the swings of manic-depressive dis-

order, especially when preceded or followed by a rebound of elation and hyperactivity. Episodes of syncope in migraine may be regarded as hysterical dissociation, particularly when the impairment of consciousness is not profound and is preceded by a dramatic train of symptoms. In all such variants the true situation is usually revealed by the development of headache later in the attack or by a history of more typical migraine attacks in the past.

Treatment

Details of medical treatment are dealt with in the reviews by Goadsby (2006) and Silberstein (2004). Triptans, selective 5HT_{1B/1D} receptor agonists, have markedly improved control of migraine for many sufferers. They are used in the treatment of the acute attack, and can work even if given several hours after the onset of headache. In addition to relieving headache they have beneficial effects on nausea and photophobia. They are usually given orally, but alternative routes of administration, including nasal spray and suppositories, may be needed when nausea and vomiting are present. Sumatriptan has been followed by a range of newer agents. Triptans may be contraindicated in patients with ischaemic heart disease, uncontrolled hypertension and in pregnancy. A recent evidence-based review suggested that alternative treatments for acute migraine included aspirin in combination with metoclopramide, and ergotamine either by nasal spray or rectally (Tfelt-Hansen 2006). An exciting new class of drugs, developed from translation of laboratory work into clinical practice, are the CGRP antagonists; one clinical trial demonstrated that these agents may be effective in treating acute migraine (Olesen *et al.* 2004).

Prophylactic drug therapy may be indicated when two or more attacks are regularly experienced per month (Bigal & Lipton 2006). Those preventive drugs that receive an evidence-based stamp of approval, both in terms of efficacy and with relative lack of side effects, include valproate, amitriptyline, propranolol and timolol (Tfelt-Hansen 2006). Propranolol is widely regarded as the drug of first choice for prophylactic treatment, and has been shown to be effective in a high proportion of patients. Other drugs with good evidence of efficacy but with problematic side effects include methysergide and pizotifen.

However, pharmacological aspects are merely a part of the total management required in patients with migraine of disabling severity. Attention may need to be directed towards a host of factors specific to the individual: regularisation of sleep and meal times, judicious avoidance of stress where this is possible, and perhaps attention to provocative substances in the diet. In addition, social and psychological factors will usually warrant close consideration when attacks have become frequent and incapacitating.

It is important to detect and treat depressive or anxiety states that are aggravating the situation (Griffith & Razavi

2006). A recent study suggests that buspirone, a 5HT_{1A} agonist, may be effective in reducing headache in migraine patients suffering anxiety (Lee *et al.* 2005). One must similarly be alert to sources of emotional turmoil that have arisen, especially conflicts at work or in interpersonal relationships. When the patient's personality and life situation are well understood, the attacks may be seen as providing oblique expression for various feelings and moods that are denied expression in other ways: imposing a halt after prolonged activity, allowing temporary respite for the working through of stresses and conflicts, providing an outlet for repressed anger, or fulfilling a self-punitive role in chronically depressed individuals (Sacks 1970). Mitchell (1971) has indicated the value which may be obtained from behaviourally orientated techniques in reducing the frequency and severity of attacks. Training in relaxation has been shown to produce enduring improvement, likewise hypnosis aimed at reducing tension or apprehension (Lance 1993). Occipital nerve stimulation may prove to be useful for patients with chronic migraine (Matharu *et al.* 2004).

Subdural haematoma

The majority of subdural haematomas follow head injury. Subdural haematomas are regarded as acute if less than 1 week old or chronic if more than 1 month old. Chronic subdural haematomas have a prevalence of about 1 in 10 000; in 25–50% of cases no history of head trauma is found (El-Kadi *et al.* 2000). Predisposing factors include alcohol, blood dyscrasias or anticoagulant treatment, ventriculoperitoneal shunt and epilepsy. Blood accumulates in the subdural space from rupture of veins running between the cortex and the dural venous sinuses. It becomes encysted between the dura and arachnoid and may swell by osmosis to reach a very large size. Localising signs often remain minimal, however, since the brain is compressed from without. The collections usually lie over the frontal or parietal lobes and are bilateral in one-third to half of cases.

Those which declare themselves acutely after head injury present either with failure to regain consciousness or with fluctuating confusion and torpor often lapsing into coma. Hemiparesis and ocular changes are usually evident, but neurological deficits can be surprisingly slight and overshadowed by the mental disturbance. Quite often the haematoma is suspected only because the patient's recovery from the injury is slower than expected.

However, it is chronic subdural haematoma that is notorious for leading to mistakes in diagnosis, particularly among the elderly. The antecedent head injury may be trivial and go unrecognised, and there may be few clear pointers to the presence of a space-occupying lesion within the skull. Sometimes there is a latent interval of days, weeks or months after injury before the declaration of symptoms. Very occasionally a year or more may elapse. This picture, with a long interval between injury and presentation, is more typically seen in

older patients. Younger patients tend to present earlier and with symptoms and signs of raised intracranial pressure such as vomiting, headache and papilloedema (Machulda & Haut 2000).

In classic examples there is vague headache that sets in gradually and may or may not be localised. It may be present only intermittently or occasionally be entirely absent. Dullness, sluggishness and difficulty with concentration slowly increase in severity. Lapses of memory and episodes of mental aberration occur. The level of consciousness fluctuates widely, with periods of apparent normality alternating with periods of drowsiness, changing from day to day or even from hour to hour. The variability in the mental state is often the most important indicator of the condition. Physical signs may be few, with inequality of the pupils, transient ocular paralyses or upgoing plantar responses. Pyramidal tract involvement may progress to hemiparesis, and a grasp reflex may be present. Papilloedema remains absent in a large proportion of cases. Epileptic fits may occur but are rare (Ohno *et al.* 1993). Ultimately the patient lapses into intermittent mutism or semicoma, but even at this stage evidence of neurological involvement can be surprisingly slight.

In a study of patients before and after surgery, reductions in thalamic blood flow were associated with impairment of conscious level and alertness, and consequently mentation (Tanaka *et al.* 1992). Reductions in cerebral blood flow (CBF) were most pronounced in thalamus and putamen before surgery. After surgery the biggest improvement in blood flow was seen in thalamus, and this improvement correlated with improvements in cognition. Patients with chronic subdural haematoma with altered conscious level or dementia, compared with those presenting with headache or motor symptoms, may have greater reductions in blood flow bilaterally in thalamus and ipsilaterally in frontal cortex (Inao *et al.* 2001). Reduced thalamic blood flow was related to the degree of midline shift.

Wide variation may be seen from the typical picture. Occasional patients present with severe headache but no physical signs, others with episodes of confusion and restlessness. In long-standing cases there may be insidious failure of intellect progressing to generalised dementia. In a retrospective survey, Black (1984) analysed the mental changes recorded in 79 patients discharged from hospital with subdural haematomas. In 20% mental symptoms had been the initial manifestation, and 58% had developed them by the time of admission. Delirium occurred in 24 patients, with lethargy and fluctuating clouding of consciousness. Dementia was present in seven, coma in six and three patients showed depression with minimal changes in consciousness or intellect.

Problems with diagnosis are particularly severe among the elderly, where the classic picture has been found to be the exception rather than the rule, occurring in only 5 of 52 examples reported by Bedford (1958). The typical story was of an aged person, already somewhat enfeebled, recently becom-

ing mentally confused. Drowsiness was not always present, and concomitant disease such as pneumonia, uraemia or cardiac failure provided further diagnostic distractions. The diagnosis may therefore be overlooked until the patient declines and becomes somnolent or comatose. Despite the utmost vigilance, only 40% of Bedford's cases were diagnosed during life.

In a psychiatric hospital post-mortem study, Cole (1978) found subdural haematomas to be the commonest form of space-occupying lesion. Six acute and eight chronic haematomas were discovered among 200 routine post-mortems, yet the diagnosis had been made before death only once. In the chronic cases particularly, signs were often minimal and fluctuation of consciousness had rarely been conspicuous. A terminal seizure or sudden death had sometimes been the first indication of a change in the patient's condition. In the elderly a cerebrovascular accident had often been held responsible when neurological deficits were present.

Apart from dementia, differentiation must be made from cerebral infarction, cerebral tumour and alcoholism. Important features distinguishing subdural haematomas from strokes are the slow steady increase in neurological deficit, the presence of some lack of responsiveness, and lack of improvement mentally despite comparatively slight physical disability (Carter 1972). Sometimes the two occur together when cerebral infarction has led to a fall with striking of the head. Cerebral tumour may be closely simulated when there is evidence of raised intracranial pressure. The fluctuating course of the drowsiness and mental confusion can then be an important differentiating feature. Chronic alcoholism may lead to similar drowsiness and intermittent mental aberration, and alcoholics are liable to head injuries which are then forgotten. Thus 7 of 14 examples of subdural haematoma discovered by Selecki (1965) among patients admitted to a psychiatric hospital were in deteriorated chronic alcoholics.

CT will usually provide definitive evidence, showing displacement of midline structures, obliteration of the ventricle on the ipsilateral side and a low-density area underlying the skull. However, care must be taken, particularly with bilateral haematomas, which can sometimes be missed by CT (Davenport *et al.* 1994). The clotted blood is initially more dense than brain, becoming hypodense as it liquefies; it therefore passes through an isodense phase during the transitional period. Clues may lie in the generalised absence of sulci and a small ventricular system, but such signs are often equivocal. MRI has been shown to be greatly superior to CT, particularly in the demonstration of small subdural collections (Williams & Hogg 2000). In general, acute subdural haematomas are low signal and hypointense compared with brain on T2 MRI sequences, and isointense or hyperintense on T1 sequences; conversely, most chronic subdural haematomas are hyperintense on T2 sequences. Subdural haematomas with high signal on T1 sequences may be less likely to rebleed after surgery.

Evacuation of the haematoma can lead to excellent results, particularly in early cases. However, much depends on the presence of complicating pathologies, and the prognosis often proves to be poor in the elderly. Other factors that predict worse outcome are greater depth of coma at presentation and longer interval between the head injury and detection of the haematoma (El-Kadi *et al.* 2000). Mehta (1965) stressed the high morbidity among survivors, particularly by way of organic mental impairments. However, more recent follow-up studies find that the majority of cases treated for chronic subdural haematoma emerge with little if any disability, and only 10–20% have moderate or severe disability. These better outcomes probably reflect earlier detection and better surgical techniques. One small follow-up study of patients treated for chronic subdural haematoma only found retrieval-based memory deficits compared with controls (Machulda & Haut 2000). Another study of 26 patients requiring surgery for chronic subdural haematoma found that half of the 18 patients who had scores in the dementia range on MMSE preoperatively made a full psychological recovery after surgery (Ishikawa *et al.* 2002).

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a multiorgan autoimmune connective tissue disorder. The helpful review by D'Cruz (2006) describes the various clinical presentations and gives a broad overview of the condition, whereas that by D'Cruz *et al.* (2007) is valuable for those who need more detail about pathogenesis and treatment. SLE and antiphospholipid syndrome overlap both clinically and immunologically, and therefore some of what follows should be read alongside the discussion of antiphospholipid syndrome (see below).

Identification of anti-DNA antibodies is critical to diagnosis and allows SLE to be distinguished from other disorders such as rheumatoid arthritis and scleroderma. Cerebral involvement is prominent in a high proportion of cases. Moreover, it is evident that very occasionally neuropsychiatric complications can set in early, before the involvement of other systems is clinically obvious. Hence it has become important to include appropriate screening tests in the detailed evaluation of certain neurological and psychiatric patients as described below.

The disease is markedly more common in females, with a female to male ratio of 9 : 1. It mainly occurs in young adult life, with a mean age of onset of 30 years, but the range is wide. There is marked variation in rates across ethnic groups, so that for example the prevalence in white Americans is less than 10 per 100 000, whereas for Afro-Caribbean people it is over 100 per 100 000.

Pathogenesis

Antibodies against intracellular components are probably involved in the development of tissue lesions. An interesting

study of US military personnel was able to identify the point at which people who were later to develop SLE turned autoantibody positive (Arbuckle *et al.* 2003). Thousands of healthy men and women had their blood taken and stored every 2 years over several years; 130 developed SLE. In 72 of these patients antibodies to DNA appeared on average 2.7 years before they developed clinical symptoms of the disease, and in some cases up to 9 years before. There seemed to be a surge of autoantibody activity just before illness onset, but it was also evidence that disease onset could not be predicted by antibody activity alone, and that other factors must be at play. Environmental factors include sunlight, silica and mercury, and numerous drugs (Sarzi-Puttini *et al.* 2005). Some cases seem to be precipitated by infection with Epstein-Barr virus. This may be because of molecular mimicry by the Epstein-Barr virus of Ro, a small intracellular RNA-protein complex. Ro autoantibodies are very common in SLE and among the first to be produced. They are also found in Sjögren's syndrome and are thus otherwise known as SS-A (Sjögren's syndrome A) antibodies. Using the database just described, the researchers were able to identify patients in whom the very first autoantibody produced, years before disease onset, was against Ro (McClain *et al.* 2005). Antibodies against this Ro epitope directly cross-reacted with a peptide from the Epstein-Barr virus nuclear antigen (EBNA). Thus Epstein-Barr virus infection might elicit antibodies against EBNA, which then cross-react with Ro and trigger an autoimmune reaction against Ro, and thus SLE.

One hypothesis suggests that disease arises because of a failure of the systems within the body to deal with the products of dead and dying cells (Munoz *et al.* 2005). Normally these products are rapidly phagocytosed and removed. However, in those with SLE the products of cell death are not properly cleared and instead become autoantigens that provoke an immune response, and this is particularly the case for intracellular components not normally visible to the immune system. For example, cells that are dying from apoptosis are understood to signal this fact by changes on their cell surface that indicate 'eat me' to local phagocytes. They are then silently removed without stimulating any inflammatory process. However, if the system is too slow, intracellular products of the dying cell will leak out and trigger autoantibody production. C-reactive protein (CRP) may be one of the pentraxin glycoproteins that activates the complement pathway and opsonises the dying cell for phagocytosis. CRP levels are relatively low in SLE, and an allele of one of the CRP genes has been found to be associated with the disorder. Another genetic link is with a polymorphism of the programmed cell death 1 gene (*PDCD1*).

The autoimmune hallmarks of SLE are autoantibodies against DNA, nucleus and other intracellular elements, activation of T and B cells, circulating immune complexes, and complement activation (Kyttaris *et al.* 2005). Cytokines, in particular interferon, are also involved. Some autoantibod-

ies may be associated with particular clinical presentations (Egner 2000; Sawalha & Harley 2004). As will be seen, it is the antiphospholipid antibodies, characteristic of antiphospholipid syndrome, that are particularly associated with neuropsychiatric SLE.

General clinical features

The onset is usually insidious with the development of fatigue, malaise and low-grade intermittent fever. A migratory arthritis or arthralgia ultimately develops in the majority of cases, closely resembling that of rheumatoid arthritis or rheumatic fever. Diffuse muscle aching is a common accompaniment as are painless mouth ulcers. Skin changes are frequent, although the classic butterfly eruption over the nose and cheeks is by no means always seen. Other skin manifestations include purpura, Raynaud's phenomenon and alopecia. Photosensitivity of the skin may be pronounced.

Lymphadenopathy, oedema and anaemia are often disclosed. Of the viscera, the kidneys are probably most frequently involved, also the pleura, lungs, heart and pericardium. Patients may present acutely with organ failure. Liver involvement is exceptional and gross splenomegaly rare. Anorexia, nausea, abdominal pain and vomiting are common. Hypertension is often considerable in degree and retinopathy may develop. A proportion of patients will develop antiphospholipid syndrome (see later in chapter).

The course of the disease may be acute, subacute or chronic and is generally difficult to predict. Chronic progression with repeated exacerbations and remissions appears to be a frequent pattern. It can be a recurrent mild illness with prolonged asymptomatic intervals. Worse prognosis is seen in those with multisystem involvement or multiple autoantibodies. The 5-year survival rates have improved from 50% reported in the 1950s to greater than 90% in the 1990s, with 15-year survival rates in excess of 80% in some series (Gladman 1992). This is probably attributable to earlier diagnosis, better treatment and the more frequent recognition of mild forms of the disease. Nevertheless, central nervous system (CNS) involvement still ranks with renal failure and accelerated atherosclerosis among the commoner causes of death.

Haemolytic anaemia is often accompanied by leucopenia, especially lymphopenia, and occasionally by thrombocytopenia. The erythrocyte sedimentation rate (ESR) is raised in about 90% of cases, showing an approximate correlation with the current stage of activity of the disease. Yet the CRP is often normal, giving a characteristic pattern of raised ESR and normal CRP. The detection of antinuclear antibodies by indirect immunofluorescence is the most sensitive screening test, identifying over 95% of cases (Venables 1993). In practice almost all patients with SLE have positive antinuclear antibodies at a dilution of 1:80 (Egner 2000). Antibodies to double-stranded DNA are more specific to the disorder,

being virtually restricted to SLE. Other antibodies against ribosomes, histones, ribonucleoprotein, Ro and phospholipids including cardiolipin, some of which are not specific for SLE, may be found. Biopsy of skin lesions, or occasionally renal biopsy, may give valuable confirmation of the diagnosis.

SLE carries a significant risk of accelerated atherosclerosis. Antiphospholipid antibodies, renal disease and steroid treatment may play a part in this process (Jennekens & Kater 2002), but for many it is not fully explained. Although SLE as an attributable risk for stroke is low (i.e. of all patients with stroke, only very few have SLE), nevertheless young people with stroke should be screened for SLE and antiphospholipid syndrome.

Neuropsychiatric problems in SLE

Neuropsychiatric manifestations are now being reported in up to 60% of patients with SLE, when comprehensively studied and followed for reasonably long periods of time. Indeed Hughes (1974) suggests that CNS involvement may overtake renal disease as the major clinical problem in the disorder, in that it carries a high mortality and the response to treatment is uncertain.

The neurological and psychiatric features of SLE lack any characteristic form or pattern but are as varied as other manifestations of the disease. Table 8.2 summarises six recent studies that have assessed the prevalence of various neuropsychiatric symptoms and signs in SLE. The data in the table are not based on any assessment that the symptom or sign is attributable to SLE; it is simply an assessment of whether the symptom or sign is present. As can be seen many of the neuropsychiatric accompaniments are non-specific, with high rates for example of headache and mood disorders. Indeed some authors (Denburg *et al.* 1997) highlight the rather non-specific nature of neuropsychiatric SLE and suggest that the rates of some psychiatric symptoms are similar to those seen for example in general medical outpatients. When authors attempt to define the neuropsychiatric morbidity found in patients with SLE that is definitely attributable to the SLE, seizure disorder, cerebrovascular disease, neuropathy and acute confusional states feature most strongly (Hanly *et al.* 2007).

Anxiety, depression and sleep disturbance are common, but may not be very different from the rates found in other rheumatology patients (Pincus *et al.* 1999). However, Ganz *et al.* (1972) showed that depression was chiefly responsible for the increased incidence of psychiatric disorder in SLE compared with rheumatoid arthritis. In patients with SLE, depressive symptoms were twice as common as organic mental symptoms, occurring in 51% and 22% respectively. In a more recent study of 52 patients with SLE but without overt neuropsychiatric symptoms compared with 29 patients with rheumatoid arthritis, those with SLE were more depressed

and more distressed (Kozora *et al.* 2005a). At least some of the sleep disturbance found in SLE is probably due to pain (Gudbjornsson & Hetta 2001) or depression (Costa *et al.* 2005). Fatigue is a common symptom in SLE (Wysenbeek *et al.* 1993) and is associated with reduced aerobic fitness and muscle strength (Tench *et al.* 2002).

Some authors suggest that neuropsychiatric symptoms may appear several years before the diagnosis of SLE, but here again the matter of attribution has to be taken into account; many of those symptoms might have been present even if the patient had never developed SLE. Nevertheless, in some cases there is good anecdotal evidence for psychiatric disturbance as the presenting feature. Lim *et al.* (1988) reported a patient who presented with acute behavioural change, paranoid ideas and a degree of impairment of consciousness, and who was soon afterwards found to have SLE with renal involvement. Three further psychotic episodes coincided with recurrences of physical symptoms. Hopkinson *et al.* (1992) discovered three cases of SLE on routine screening of 296 admissions to acute psychiatric units. In the series of Lim *et al.* (1988), 12% of patients with SLE had a psychotic illness at some stage. The point prevalence of psychosis is much lower, of the order of 2–5%, and in many of these cases occurs in the context of a delirious state (Ovsiew & Utset 2002).

In the past delirium was probably the most frequent of the mental abnormalities. For example, it was present at some time or another in approximately 30% of patients in Heine's (1969) series. Often referred to as 'lupus psychosis' it would last for hours or days, then subside completely. The picture may be of quiet confusion and clouding of consciousness, or more florid delirium with visual and auditory hallucinations and excessive motor activity (Johnson & Richardson 1968). The degree of disorientation and memory impairment may fluctuate markedly from time to time. However, more recent studies (see Table 8.2) find only about 3% with acute confusional states. This presumably reflects earlier diagnosis of SLE, such that much milder cases are now forming the majority. In this setting mood disorders become the most common of the mental disorders to be found (Table 8.2).

Cognitive impairment is usually mild, often evanescent, and similar to that seen in subcortical disease. Attention and concentration, memory and processing speed are most vulnerable, followed by executive and visuospatial problems. For example, in cases that show cognitive impairment only 5% of patients are found to have 'cortical' deficits on MMSE (Leritz *et al.* 2000). Of patients with evidence of CNS involvement, 75% will have some degree of cognitive impairment compared with about 25% of those without other evidence of neuropsychiatric SLE (Carbotte *et al.* 1986; Kozora *et al.* 1996). The degree of impairment is also related to overall disease activity, so that patients with severe disease, whether or not it involves the CNS, are more likely to show impairment (Sweet *et al.* 2004). There is no consistent evidence that steroid use

* When defined, chorea is most common.

[†] Assessed using battery of neuropsychological tests.

plays much of a role, although the occasional study does find greater cognitive impairment in those taking steroids (McLaurin *et al.* 2005); however this may simply be because use of steroids is a surrogate marker of more severe disease. In those without clinically manifest CNS disease it may be difficult to link cognitive impairment to findings on cerebral imaging. In this setting one study found 35% to have enlarged ventricles or white matter hyperintensities, and 35% to have neuropsychological impairment, but the two were not closely related (Kozora *et al.* 1998).

Cognitive impairment is often found to be associated with the presence of psychiatric problems, particularly depression. In one study, as the psychiatric illness improved over time so did the cognitive impairment (Hay *et al.* 1994). Perhaps this is why other follow-up studies have also found a good proportion of those with cognitive impairment when first seen to be performing in the normal range a year or two later (Hanly *et al.* 1994). In another study, 123 patients were assessed every 4 months over at least 3 years on a battery of computerised neuropsychological tests particularly involving psychomotor speed (McLaurin *et al.* 2005). Over time there was a marked improvement in test scores, presumably at least partly due to practice effects. Stable scores were found in a follow-up of 51 stable patients, seen for their second evaluation on average 20 months after the first (Carlomagno *et al.* 2000). Of the 51 patients, 15 had cognitive impairment and in 14 this was still present at 20 months. Not one of the 15 cases deteriorated, although four patients had developed cognitive impairment in the mean time. Even after 5 years there is no evidence for progressive deterioration (Waterloo *et al.* 2002); as a group, 28 patients showed no change in the majority of neuropsychological test results, and in fact on two of the nine tests they showed improved performance at 5 years.

It seems likely that mild cognitive impairment is more vulnerable to psychological state and more likely to remit compared with more severe impairment that tends to be constant over time, and is better explained by the severity of SLE, particular if it affects the CNS, and its treatment. This divergence may explain the apparently contradictory findings of studies which have looked at psychiatric predictors of cognitive impairment in patients with SLE (Harrison & Ravdin 2002). As many studies find an association, particularly with depression or psychological distress, as fail to find an effect. For example, in a small study of 11 depressed SLE patients compared with seven non-depressed patients, no differences were found on neuropsychological test performance (Denburg *et al.* 1997). Moreover, in 20 patients assessed during a flare-up of their SLE, eight had a psychiatric diagnosis, largely anxiety disorder with or without panic disorder (Segui *et al.* 2000). A year later when the disease was no longer active, only two remained psychiatrically unwell. However, cognitive impairment, assessed using the rather crude MMSE, showed no change over the year despite the improve-

ment in mental health. This finding is in contrast to that of Hay *et al.* (1994) (see earlier). Furthermore, in a careful study comparing 52 patients with SLE but without neurological involvement with 27 patients with neuropsychiatric SLE and with controls, depression was found to be the best predictor of cognitive impairment (Monastero *et al.* 2001). The neuropsychiatric SLE patients had higher scores on both depression and anxiety measured using the Hamilton Depression Rating Scale and the Hamilton Anxiety Rating Scale. However, no significant differences were found between the two SLE groups on the neuropsychological test battery, although the neuropsychiatric patients tended to be worse on all measures. In a multivariate analysis the patient's score on the Hamilton Depression Rating Scale was the only clinical variable to predict severity of cognitive impairment. More recently, Kozora *et al.* (2006) compared 22 patients with neuropsychiatric SLE with 31 non-neuropsychiatric SLE and healthy controls and found that symptoms of depression, fatigue, pain and complaints of cognitive dysfunction were more common in SLE, although only objective cognitive impairment was greater in the neuropsychiatric SLE cases. Within the cases with neuropsychiatric SLE the four symptoms of depression, fatigue, pain and objective cognitive impairment were all associated with one another, an association not seen in the other SLE cases nor in controls. The authors suggested a single common aetiology might explain this symptom cluster.

Headache is perhaps the most common of all neurological problems encountered in the disease, often with features typical of migraine (McCune & Golbus 1988), with about half of migraine patients having aura. However, it may be difficult to be confident that the headache is due to SLE (Hanly *et al.* 2007). A review of headache in SLE concluded that although 32% of SLE patients reported migraine and 23% tension-type headache, there was little evidence that these rates are different from those in controls (Mitsikostas *et al.* 2004).

Seizures, ischaemic strokes and TIAs, and neuropathies are the common neurological manifestations of SLE (see Table 8.2). In contrast, in antiphospholipid syndrome the neurological picture is dominated by ischaemic strokes and TIAs (Table 8.3). The conditions overlap. Strokes are more likely in antiphospholipid antibody-positive SLE than antiphospholipid antibody-negative SLE. Some of this increased risk may be because patients with SLE who are antiphospholipid antibody positive are more likely to have heart valve disease (Khamashta *et al.* 1990). Furthermore, patients with antiphospholipid syndrome are most likely to have epilepsy if they also have SLE; in primary antiphospholipid syndrome 6% of patients have epilepsy, whereas when antiphospholipid syndrome is secondary to SLE the rate is 13% (Shoenfeld *et al.* 2004). In fact it seems likely that patients with both SLE and antiphospholipid syndrome are at greatest risk of neuropsychiatric sequelae. For example, in

Table 8.3 Neurological disorders occurring at some stage in 1000 patients during the course of antiphospholipid syndrome. (From Cervera *et al.* 2002.)

	Number of patients
Migraine	202
Stroke	198
Transient ischaemic attack	111
Epilepsy	70
Multi-infarct dementia	25
Chorea	13
Acute encephalopathy	11
Transient amnesia	7
Cerebral venous thrombosis	7

667 patients with SLE neuropsychiatric problems were more common in the 15% with a comorbid diagnosis of antiphospholipid syndrome (Alarcon-Segovia *et al.* 1997). There was no good evidence that any particular neurological manifestation was selectively affected, although cerebrovascular disease was the only condition that was statistically more common in antiphospholipid syndrome-positive SLE.

In SLE, cranial nerve palsies are among the commoner neurological signs. Usually they set in suddenly without prodromes and most are transient. Disorders of external ocular movement, pupillary abnormalities and vertigo are the most frequent, more rarely disorders of the fifth, seventh and bulbar nerves. Visual field defects are often partly due to retinal changes. Papilloedema may result from a local retinal lesion and optic atrophy may follow. Peripheral neuropathy is usually symmetrical and distal, with both sensory and motor deficits. Chorea is probably the most common of the movement disorders, but these also include tremors, parkinsonian rigidity and ataxia due to brainstem lesions. All are relatively rare. Choreiform movements in association with SLE may at first be diagnosed as Sydenham's chorea. Paraparesis due to transverse myelitis of the cord occurs infrequently. The neurological symptoms and signs of SLE may therefore sometimes resemble those found in multiple sclerosis, so for example optic neuropathy and internuclear ophthalmoplegia are common to both, as are CSF oligoclonal bands.

In SLE and antiphospholipid syndrome, seizures, generalised or partial, are not uncommon and often unexplained by a brain lesion visible on neuroimaging (Cimaz *et al.* 2006). In patients with SLE, those who are anticardiolipin antibody positive are more likely to have seizures. In patients with antiphospholipid syndrome, part of the increased risk of epilepsy is explained by the extent of cerebrovascular disease and, to a lesser extent, valvular heart disease. However, much of the increased risk is not related to ischaemic events, and it seems quite likely that antibodies acting on neurones

may be responsible (Shoenfeld *et al.* 2004). As already noted, patients with both SLE and antiphospholipid syndrome are at greatest risk of epilepsy, compared with SLE alone (Appenzeller *et al.* 2004) or antiphospholipid syndrome alone (Shoenfeld *et al.* 2004).

These findings have led to research into antiphospholipid antibodies in patients with epilepsy (Cimaz *et al.* 2006). However, several studies have found that antiphospholipid antibodies, anticardiolipin antibodies and lupus anticoagulant seem to be as common in control populations as they are in epilepsy. Subgroup analyses have found that higher frequency of seizures may be associated with antibody-positive status. In children there may be a better case for the association between being antiphospholipid antibody positive and having epilepsy. All such studies are complicated by the observation that some of the anticonvulsants may be associated with autoantibody production.

Hinchey *et al.* (1996) have described a posterior reversible encephalopathy syndrome in which white matter changes are found on T2-weighted MRI posteriorly in the brain (see also section on hypertensive encephalopathy earlier in chapter). Patients often present with headache, seizures and visual or mental disturbance, and the condition is associated with hypertension, renal disease and rheumatoid conditions. Diffusion-weighted MRI suggests that the high signal in white matter is due to oedema, probably vasogenic, and this is consistent with the observation that the MRI findings often improve as the condition remits. The condition is rare, but several of the cases have been in patients with SLE (Kur & Esdaile 2006; Magnano *et al.* 2006). In these patients visual loss and seizures are characteristic, severe hypertension and headaches almost always present along with renal disease, and the condition is often related to treatment with immunosuppressive drugs. The majority made a full recovery once the hypertension was treated.

Neuroimaging in SLE

Neuroimaging may be useful in the assessment of a patient with SLE by identifying lesions that are clinically silent, or clarifying the extent to which the brain has been affected when neuropsychiatric symptoms are present. Sometimes it may help to indicate the cause of the neurological disorder, for example showing that a large-vessel stroke as opposed to deterioration of diffuse periventricular white matter disease is responsible for a recent-onset confusional state. However, much of what follows is of more theoretical interest. How easy is it to demonstrate abnormalities on neuroimaging in patients with SLE, and in particular neuropsychiatric SLE? And does the picture that is found tell us about causation of symptoms?

Earlier studies suggested that MRI is not very good at distinguishing cases with neuropsychiatric SLE from those without: in both cases a good proportion, perhaps as many as

50%, have normal MRI (Tanabe & Weiner 1997). Although MRI generally could distinguish between patients with focal signs and those without, those with clinically 'diffuse' neuropsychiatric syndromes, including for example headache, seemed to have as many abnormalities as those without. In those with clinically diffuse syndromes, the non-focal lesions that were found were said to be frequently reversible with steroid treatment, suggesting they were due to oedema. However, more recent studies, reviewed by Govoni *et al.* (2004), have found MRI abnormalities to be more frequent in neuropsychiatric SLE (Sanna *et al.* 2000; Bosma *et al.* 2002). So, for example, in patients without neuropsychiatric involvement, 25–50% of patients show abnormalities; this rises to 75% in patients with neuropsychiatric SLE. Perhaps the study with the least risk of ascertainment bias is that from Finland where they were careful to ensure that all cases of SLE within the 440 000 catchment were identified (Ainiala *et al.* 2005); 43 patients with SLE, 19 of whom had neuropsychiatric SLE, were carefully matched to 43 controls from the same population database and assessed for SLE illness severity and evidence of neuropsychiatric problems. MRI scan data were blindly rated for evidence of lesions on T1 and T2 sequences and were analysed using computer software to determine CSF volume as a proportion of intracranial volume, a measure of cerebral atrophy. Patients with SLE were different from controls on all three counts; they had greater cerebral atrophy and more evidence of both T1 and T2 lesions. Furthermore, within the SLE group greater MRI abnormalities were associated with presence of neuropsychiatric SLE. In particular, patients with cognitive impairment had more severe cerebral atrophy and T2 lesions, those with cerebrovascular disease were more severely affected on all three measures, and those with seizures had worse cerebral atrophy. No other single neuropsychiatric problem was associated with MRI change. Cerebral atrophy and T1 lesions also correlated with cumulative steroid usage.

The commonest MRI finding, seen in 15–60% (Govoni *et al.* 2004), is small punctate lesions in subcortical white matter, mainly periventricular or subcortical. In the past these were sometimes regarded as evidence of vasculitis, but in fact probably represent small areas of infarction or ischaemia due to a localised vasculopathy. Other relatively common abnormalities are cortical atrophy and ventricular dilatation, periventricular white matter changes, and major infarcts. Occasionally there will be evidence of cerebral venous thrombosis. T1 lesions are more likely to represent the gliosis of infarcts and demyelinating lesions that are well established. Lesions on T2-weighted imaging are more likely to resolve, sometimes as a result of steroid therapy, and this may be because they are at least partly due to cerebral oedema. Gadolinium-enhancing lesions on MRI, suggesting a breakdown of the blood–brain barrier, are not common, but when seen also tend to disappear with treatment (Miller *et al.* 1992). It has been suggested that T2-weighted small punctate

lesions, mainly localised to white matter, represent small-vessel vasculopathy (see later).

More sophisticated MRI techniques include measures of DWI and magnetisation transfer imaging (MTI). The former relies on the signal change associated with alterations in the ability of water molecules to diffuse in the extracellular or intracellular space. In particular, early signal change on DWI may be found when intracellular oedema occurs, for example due to cerebral ischaemia. Intracellular water has a more restricted ability to diffuse and the consequent reduction in the apparent diffusion coefficient (ADC) can be seen as high signal on DWI. On the other hand, a breakdown in tissue integrity can be manifest as an increase in ADC. This is what was found in a study of 11 patients with neuropsychiatric SLE but without MRI evidence of infarcts, only allowing white matter lesions of less than 5 mm. The findings were not striking and could not be seen by direct visualisation of DWI images, but instead relied on inspection of the histogram of ADC activity across all brain pixels, showing that patients with SLE had more pixels with high ADC values (Bosma *et al.* 2003). On the other hand, in a less sophisticated study of 20 unselected cases of neuropsychiatric SLE, high signal (reduced ADC) was found on DWI, largely in association with infarcts or vasogenic oedema (Moritani *et al.* 2001).

By detecting macromolecules that have been diluted or destroyed, MTI may be more sensitive to brain damage than standard MRI measures. It is for example affected by the concentration of phospholipids and myelin. In healthy brain the signal, as expressed by the magnetisation transfer ratio (MTR), is relatively homogeneous across brain voxels. Brain damage tends to cause a decrease in and flattening of the peak of the histogram of number of voxels against activity, as found for example in normal-appearing white matter in multiple sclerosis. In SLE there is preliminary evidence that MTI may be able to detect abnormalities not otherwise evident on MRI. Rovaris *et al.* (2000) studied nine patients with neuropsychiatric SLE and 15 with SLE without neuropsychiatric involvement and were able to compare the findings with controls and patients with multiple sclerosis. The analysis was restricted to normal-appearing brain tissue by removing from the analysis pixels affected by macroscopic lesions on MRI. Normal-appearing brain tissue in patients with neuropsychiatric SLE or multiple sclerosis was similar with significantly lower peaks than those found in both controls and SLE patients without neuropsychiatric involvement. However, the authors do not take account of the fact that the neuropsychiatric SLE patients were on average about 10–14 years older than the other groups. Another study of neuropsychiatric SLE patients who did not have infarcts, probably based at least partly on the same cohort described above showing higher ADC values, found that MTI changes correlated with clinical measures of neurological, cognitive and psychiatric functioning. More recently the same group has found that these changes in the MTR

histogram peak height over time are in line with the patients' clinical condition (Emmer *et al.* 2006), and that changes in MTI appear to be related to the presence of IgM anticardiolipin antibodies (Steens *et al.* 2006).

Further support for disturbance of cerebral cellular function in SLE comes from magnetic resonance spectroscopy (MRS), which can measure the signal from several chemicals found in cerebral tissue. The neurochemical signal from *N*-acetylaspartic acid (NAA) is found almost exclusively in neurones, with lower signal suggesting neuronal dysfunction. Choline-related metabolites contribute to the Cho peak of MRS and this tends to be raised in the presence of brain injury. On the other hand, the creatine (Cr) signal is regarded as being relatively constant regardless of disease status, so is used as an internal reference. The NAA/Cr and Cho/Cr ratios are therefore regarded as measuring NAA and Cho activity respectively. In SLE there is reduced NAA signal not only in injured areas but also in normal-appearing white matter (Govoni *et al.* 2004; Appenzeller *et al.* 2006). However, within normal-appearing brain tissue it was only areas defined as hypoperfused using ⁹⁹Tc-labelled hexamethylpropyleneamine oxine (HMPAO)-SPECT that showed altered NAA/Cho and Cho/Cr ratios, lower and higher respectively, compared with areas with normal perfusion (Castellino *et al.* 2005). A lowered NAA/Cho ratio may be a particularly sensitive marker of disease activity and in 12 patients with SLE the ratio correlated with scores on cognitive testing (Brooks *et al.* 1999). However, in a small study of seven cases of SLE without neuropsychiatric involvement compared with seven controls, no differences were found between the groups on NAA/Cr despite the SLE patients having significant cognitive impairment (Kozora *et al.* 2005b). Furthermore, in a study of 90 patients with SLE, with 50 having repeat scanning after 12 months, the NAA/Cr ratio mapped more closely to SLE disease activity than clinical evidence of CNS involvement (Appenzeller *et al.* 2005).

SPECT is one of the most sensitive techniques for detecting cerebral changes in SLE (Govoni *et al.* 2004). The typical picture is of widespread multifocal areas of reduced uptake suggesting patchy perfusion, most frequently in the distribution of the middle cerebral artery. Abnormalities are found in 86–100% of patients with major symptoms of neuropsychiatric SLE, and even in patients without neuropsychiatric involvement 10–50% will show abnormalities on SPECT. Of particular interest is the ability of SPECT to reveal changes in brain tissue that appears normal on conventional MRI. Moreover, as noted above these SPECT abnormalities tally with metabolic changes, identified using MRS, in the hypoperfused but normal MRI-appearing tissue. Using ⁹⁹Tc-labelled ethylcysteinate dimer (ECD)-SPECT, global hypoperfusion particularly involving frontal and temporal lobes has been found to distinguish patients with and without CNS involvement (Appenzeller *et al.* 2007). In a study of 56 patients with SLE, mostly with mild or stable

disease, HMPAO-SPECT was compared with the results of a battery of neuropsychological tests (Waterloo *et al.* 2001). Psychomotor slowing correlated with regional CBF as measured by SPECT in parietal lobe, but could also be explained by evidence of cerebral infarcts on MRI. In fact the SPECT findings did not add to what was already known using conventional MRI. This finding runs counter to others which suggest that evidence of hypoperfusion on SPECT does explain some of the cognitive impairment of SLE that cannot be explained by manifest brain injury using conventional MRI. In support of this failure to find added value of SPECT, the authors cite studies finding poor correlation between SPECT and PET, and one study using PET which failed to demonstrate glucose hypometabolism in patients with cognitive impairment. However, one study did find changes in glucose hypometabolism using PET in patients with SLE and neuropsychiatric involvement compared to those without (Weiner *et al.* 2000). Almost all patients with significant cognitive impairment also had reduced metabolism in parieto-occipital regions regardless of findings on MRI. Another study measured regional CBF in 20 SLE patients with no history of stroke, movement disorder or dementia, and no major (i.e. >2 mm) lesions on MRI using ⁹⁹Tc-ECD-SPECT (Oda *et al.* 2005). Compared with controls reduced regional CBF was found in posterior cingulate and thalamus, but only in the seven patients with either psychosis (*N* = 3) or mood disorder (*N* = 4). This may in part reflect the changes in blood flow produced by mental symptoms.

Aetiology and pathogenesis of neuropsychiatric manifestations in SLE and antiphospholipid syndrome

Pathological changes in the brain have been abundantly described in SLE, chiefly in the form of disease of small blood vessels leading to scattered infarctions and haemorrhages. The smaller arterioles and capillaries are principally affected, with evidence of inflammatory, destructive and proliferative changes. The commonest finding at post-mortem is a small-vessel non-inflammatory proliferative vasculopathy consisting of intimal proliferation with fibrinoid degeneration in the vessel walls or hyalinisation with necrosis (Johnson & Richardson 1968; Jennekens & Kater 2002). This may be associated with microglial proliferation around the capillaries or with microhaemorrhages due to extravasation of erythrocytes and fibrin. The vascular changes are especially prevalent in the cortex and brainstem. Small vessels may show 'beading', with alternating stenosis and dilatation on angiography (Tanabe & Weiner 1997), similar to that seen in cerebral vasculitis. On the other hand, a true 'vasculitis' is only present in about 10% of cases (Belmont *et al.* 1996). Cerebral SLE can therefore be understood as a diffuse but patchy microvascular disorder, and this explains why multiple fairly localised perfusion defects are seen on SPECT (see

earlier). This small-vessel cerebral angiopathy probably explains the cognitive impairment of patients who otherwise have no neuropsychiatric involvement (Jennekens & Kater 2002). Infarcted areas are usually small and multiple, although extensive areas of softening and large intracerebral haemorrhages occasionally occur. Serum S-100B levels are raised in SLE, particularly in those with neuropsychiatric involvement, probably because of ongoing neuronal damage (Schenatto *et al.* 2006).

Clinicopathological correlations at post-mortem are far from exact. O'Connor and Musher (1966) found that gross impairment of CNS function could exist with no demonstrable lesions at post-mortem; conversely, patients without neuropsychiatric manifestations could show widespread cerebral pathology. Other factors such as uraemia, electrolyte disturbance and hypertension may therefore make their own contributions to mental disturbance.

An additional mechanism may depend on immunological reactions that implicate brain tissue. Thus a review of cerebral inflammation and degeneration in neuropsychiatric SLE suggests that brain-specific autoantibody production, immune complex deposition, and intrathecal production of proinflammatory cytokines are likely to be involved (Trysberg & Tarkowski 2004). The best evidence is for the role of antiphospholipid and anticardiolipin antibodies and lupus anticoagulant (Sanna *et al.* 2003). Antiphospholipid antibodies increase the likelihood of large-vessel cerebrovascular disease, and also probably contribute to the small-vessel vasculopathy. Whether in addition they have direct effects on neuronal tissue is uncertain, although this is a case frequently made for anticardiolipin antibodies. For example, antiphospholipid antibodies have been shown to bind to neuronal tissue, causing membrane depolarisation of synaptosomes (Chapman *et al.* 1999). Moreover, anticardiolipin antibodies may interact with the GABA receptor-mediated chloride channel of snail neurones (Liou *et al.* 1994).

Other immunological markers that have been associated with neuropsychiatric SLE include the proinflammatory cytokine interleukin (IL)-6. A recent review found that 20 autoantibodies had been studied in SLE and antiphospholipid syndrome, 11 being specific for brain and nine systemic (Zandman-Goddard *et al.* 2007). The review suggests that cognitive impairment, psychosis and depression could often be linked to one or other of these antibodies. However, the review did not take account of the many studies with negative findings. For example, early suggestions that antiribosomal P antibodies are particularly associated with neuropsychiatric disorder have not been confirmed (Gerli *et al.* 2002).

There has been recent interest in antibodies to *N*-methyl-D-aspartate (NMDA) receptors. Antibodies to double-stranded DNA are one of the hallmarks of SLE, and in some patients a subset of these antibodies may cross-react with the ligand-binding domain of the NMDA receptor (Kowal *et al.*

2006). In mice these anti-NMDA receptor antibodies cause neuronal apoptosis. In a clinical study, although there was no effect of anti-NMDA antibody activity on cognitive impairment, high titres were associated with depression; 6 of 11 patients with depression had high titres, whereas only 10 of 48 non-depressed patients did (Lapteva *et al.* 2006).

Considerable attention has been given to the possible role of steroids in precipitating confusional episodes, with a consensus of opinion that they can only rarely be held responsible. Thus similar episodes were often reported before steroids were introduced, they continue to be reported in patients not having such treatment, lowering of the dose has an inconsistent effect, and episodes do not necessarily recur when steroids are given again during later relapses. Nevertheless, the possibility must be borne in mind that steroids may occasionally have an aggravating or precipitating effect.

Neuropsychiatric SLE may produce changes in the cortical organisation of psychomotor processing. Patients without any neurological involvement of their right arm, and with no lesion on MRI affecting the left pyramidal tract, were studied using fMRI. When asked to move their right arm under test conditions they showed a larger area of activation of contralateral sensorimotor cortex than did normal controls (Rocca *et al.* 2006).

Treatment

The treatment of SLE is best undertaken by experts, particularly as there is now a variety of new immunosuppressant agents available. Current practice is outlined by D'Cruz *et al.* (2007). In addition to specific treatment, patients should be warned to avoid undue exposure to the sun, and intercurrent infections should be treated promptly since they can lead to exacerbations. Preparations containing estrogen, such as the contraceptive pill, are best avoided partly because they may cause the disease to flare up and partly because of the increased risk of thrombotic events.

Steroids remain one of the mainstays of treatment for the systemic effects of the disease and are also important in managing certain neuropsychiatric developments. Prednisolone is used most commonly. Cyclophosphamide can be very successful, for example in those with renal disease, but has worrying side effects. Mycophenolate mofetil, a drug that inhibits B and T cell proliferation as well as having other immunosuppressive actions, has been introduced and will probably replace cyclophosphamide for the treatment of renal SLE because it is far better tolerated and probably more effective. Rituximab, a monoclonal antibody directed against B cells and used in lymphoma, has the potential to produce remissions, perhaps when other treatments have failed.

The management of neuropsychiatric manifestations can prove difficult, though fortunately most episodes are transient and self-limiting. Special attention must be paid to clouding of consciousness or mild intellectual impairment in

what appear at first sight to be non-organic disturbances. EEG and MRI can be helpful in deciding the likelihood of an organic cerebral cause, but are not an accurate guide in every case. Other causes must be carefully considered: uraemia, electrolyte disturbance, hypertension, infection or steroid administration. In a prospective survey of 36 episodes of cerebral disturbance, Wong *et al.* (1991) considered that active SLE was responsible in less than one-quarter of cases, with infection, steroids or hypertensive encephalopathy accounting for the remainder. When confusion or delirium appear with fresh relapses of the disorder, steroids may help considerably in their resolution. On other occasions, however, they may stand to aggravate rather than help the clinical picture, some psychotic episodes responding to a reduction in current dosage.

For patients who are reasonably stable, physical exercise appears to be helpful. Tench *et al.* (2003) studied 93 reasonably stable but largely sedentary patients who were randomised to receive an exercise programme, a relaxation programme or treatment as usual. Those in the exercise programme were asked to exercise, for example by going for a walk, for at least 30–50 minutes at least three times a week. After the 12-week treatment, significantly more patients in the exercise group rated themselves as having less fatigue and at least ‘much improved’ on the Clinical Global Impression Scale, compared with either the relaxation or treatment as usual group. It is therefore important to consider opportunities for exercise alongside other psychosocial issues. Matters such as the home environment and financial responsibilities have to be considered, as do the needs of the family. The attitudes of clinicians may have large impacts on quality of life, and good communication between doctor and patient, as in any condition particularly when long-lasting, is crucial (Seawell & Danoff-Burg 2004).

Vasculitis of the central nervous system

Vasculitis is inflammation of the blood vessel wall and is synonymous with angiitis. The classification of vasculitis has changed over the years. Recent insights into the pathogenesis of these conditions have led to a reappraisal of the best way to classify vasculitis, in particular as it affects the nervous system. Even though there is no universal agreement on the terms to be used, most authorities now agree on the value of a classification that acknowledges the size of the vessels preferentially affected, the presence or absence of autoantibodies, and whether the condition affects the CNS in isolation or is accompanied by systemic disease (Carolei & Sacco 2003; Younger 2004) (Table 8.4). It is accepted that regardless of which system is used the categories will overlap to some extent with one another.

Systemic vasculitis is usually referred to as primary when no cause for the condition in terms of infection, drugs or malignancy is found (Zandi & Coles 2007). Some authors

Table 8.4 Vasculitis involving the CNS.

<i>Systemic vasculitis (generally involves multiple organs including the CNS)</i>	
Small vessels (arterioles, capillaries and venules) (generally ANCA positive)	Wegener’s granulomatosis*
	Microscopic polyangiitis*
	Churg–Strauss syndrome*
	Henoch–Schönlein purpura†
Medium-sized vessels (medium and small arteries)	Polyarteritis nodosa
Large vessels (arteries) (ANCA negative)	Giant-cell (temporal) arteritis
	Takayasu’s arteritis
<i>Vasculitis confined to the CNS‡</i>	
Primary angiitis of the CNS	Granulomatous angiitis of the CNS
	Benign angiitis of the CNS

Note that there are more patients with vasculitis involving the CNS as a result of a systemic vasculitis than there are patients with a vasculitis confined to the CNS.

* One of the primary small-vessel vasculitides (Pavone *et al.* 2006).

† Often regarded as a hypersensitivity vasculitis, e.g. following drug administration, ANCA negative, IgA complex positive.

‡ In some cases of systemic vasculitis, the vasculitis is found only in the CNS.

ANCA, antineutrophil cytoplasmic antibody.

suggest that vasculitis associated with the connective tissue disorders, for example when occasionally seen in SLE or rheumatoid arthritis, should also be regarded as secondary. Conditions that mimic vasculitis, such as infective endocarditis or mitochondrial disease, need to be excluded.

The vasculitides that affect the CNS can also be regarded as primary and secondary. However, in this case, ‘primary’ means there is no systemic vasculitis to explain the CNS involvement (Table 8.4). Vasculitis of the CNS, in the absence of systemic involvement, is usually called primary angiitis of the CNS, although others refer to it as idiopathic or isolated angiitis of the CNS. Certain principles are generally common to all the cerebral vasculitides.

- There is a very pleomorphic clinical picture: acute or insidious onset; diffuse, focal or multifocal signs and symptoms; single incident or relapsing/remitting. Presentations may include headache, delirium, seizures, subarachnoid haemorrhage, strokes/TIAs, focal neurological symptoms and signs, cranial neuropathies, cord lesions, peripheral neuropathy (particularly mononeuritis multiplex), or psychosis or mood disorder.

- Psychiatric sequelae are related to encephalopathy, focal cortical lesions and psychological reaction to illness.

- It is necessary to have a high index of suspicion; the vasculitides are rare but treatable.

- They are often accompanied by general systemic symptoms, malaise, fever and weight loss. In systemic vasculitis, any organ may be affected but particularly kidney. Systemic vasculitis with secondary involvement of CNS is more common than primary vasculitis (angiitis) of the CNS.
- Acute-phase markers, ESR and CRP, are often raised. Antineutrophil cytoplasmic antibodies (ANCA) are sometimes present.
- MRI shows diffuse cortical and deep white matter ischaemic lesions, strokes or subarachnoid haemorrhage, or gadolinium meningeal enhancement.
- CSF shows increased protein and moderate pleocytosis; there may be oligoclonal bands.
- There is a need to exclude other diseases, particularly those that closely mimic vasculitis.
- Angiography shows characteristic beading of arteries, and sequential stenosis and ectasia (dilatation), but this is non-specific unless it involves multiple vessels in multiple vascular territories.
- Biopsy is the definitive diagnosis, but there may be false negatives when vasculitis is focal. Cerebral, meningeal, nerve or arterial biopsy should be taken. Diagnosis may be based on biopsy of another organ, e.g. renal biopsy.
- The vasculitides generally respond to treatment with steroids with or without cyclophosphamide or other immunosuppressive agents.
- Without treatment there is high morbidity and mortality. Therefore there is a high potential for avoidable mortality and morbidity.

Vasculitis, both systemic and involving the CNS, may be secondary to infection, malignancy or drugs (Siva 2001). Viral infections that commonly cause a vasculitis include human immunodeficiency virus (HIV), cytomegalovirus (CMV), varicella-zoster, herpes simplex, and hepatitis B and C. Various bacterial infections may be responsible and include of course *Treponema pallidum* and *Mycobacterium tuberculosis*, but also *Haemophilus influenzae* and *Borrelia burgdorferi* (the cause of Lyme disease). Fungi, such as *Aspergillus*, and protozoa, such as malaria and *Toxoplasma*, should also enter the differential diagnosis.

CNS vasculitis has also been reported in patients with lymphoma and Hodgkin's disease as well as leukaemia. It may occur as a hypersensitivity reaction to drugs. Cerebral vasculitis has been reported in amphetamine abusers and there are anecdotal reports of vasculitis in cocaine and other drug users. However, the evidence that drugs of abuse cause a vasculitis is not strong. Firstly, it is unusual to have confirmation that any vascular event or angiopathy is in fact due to a vasculitis. Secondly, even if it is a vasculitis, it is necessary to rule out other causes of vasculitis such as endocarditis, HIV, hepatitis B or syphilis. The best evidence for drug-induced vasculitis is probably for cocaine, amphetamine and related drugs that produce vasoconstriction (Siva 2001).

Although less than 5% of strokes are due to vasculitis, in the young patient with stroke vasculitis should be considered. Vasculitis should also be a differential diagnosis in any neuropsychiatric case in which steadily accumulating evidence of organicity is found in a patient who originally presented with unremarkable psychiatric symptoms. The following case vignette is typical of the uncertainty that surrounds many such cases.

A 28-year-old man presented with a year's history of treatment-resistant atypical depression, with boredom and finding life meaningless. Increasing euphoria, personality change with disinhibition, accompanied by fleeting diplopia and headaches, developed over the course of several months. An early CT brain scan was negative. He then presented with a sudden onset of dysarthria, left hemiplegia, right cerebellar ataxia and ophthalmoplegia. MRI showed a large T2 high-signal lesion in the right basal ganglia. Brain biopsy excluded a lymphoma but failed to confirm a vasculitis because no vessels were to be found in the small fragments of biopsy material. All other investigations were also negative, although an angiogram was not performed. Five months later he deteriorated with a similar lesion in the right pons extending into the midbrain and temporal lobes. This appeared to respond to treatment with steroids, as did a subsequent relapse a few months later. The presumed diagnosis was a primacy angiitis of the CNS (Hocaoglu & Tan 2005).

Primary angiitis of the nervous system

Primary angiitis of the CNS (PACNS) has evolved as a diagnostic entity over the last 50 years since the original descriptions of a granulomatous angiitis restricted to the nervous system (Calabrese 2001). These conditions are exceedingly rare but are important to neurology and psychiatry in that they can affect the nervous system alone without evidence of vasculitis elsewhere. As cases have accumulated, and with MRI allowing enhanced case ascertainment, the initial gloomy prognosis has been modified. Cases have been described that lead a relatively benign course, even without treatment. Some authors separate PACNS into benign angiitis of the CNS and the more typical granulomatous angiitis of the CNS (Calabrese 2001). However, these two entities overlap considerably, with more features in common than set them apart. PACNS should be considered when after extensive investigation a patient has unexplained neurological problems. There then needs to be evidence of a cerebral arteritis, and evidence that this is confined to the CNS. Disorders capable of mimicking a cerebral vasculitis need to be excluded.

Sigal (1987) reviewed the 61 cases in the literature to that date. Men were affected slightly more often than women, although recent studies show an equal male–female ratio. The mean age of onset was 46 years, but the range is wide with cases reported in childhood and old age. Presentation is often remarkably non-specific, with the acute or subacute onset of headache, confusion and memory disturbance. The most common presentation is headache with encephalopathy plus multifocal signs (Siva 2001). Cognitive impairment, which may progress to a dementia, and alterations of personality and other psychiatric symptoms can be to the fore. Other neurological sequelae include cranial neuropathies, intracerebral or subarachnoid haemorrhage (Kumar *et al.* 1997), seizures and less commonly strokes or spinal cord disease. Meningeal involvement may be prominent. Non-specific symptoms of malaise, nausea and low-grade fever occurred in a significant proportion of cases. The onset is often insidious, and followed by a relapsing/remitting course. The picture may initially suggest encephalitis, cerebral tumour, meningovascular syphilis, multiple sclerosis or sarcoid of the nervous system. The vasculitis may be secondary to infection, particularly with varicella-zoster virus, HIV, CMV and hepatitis B or C.

The ESR may be normal and is more likely to be raised if there is small-vessel involvement. The CSF typically shows increased protein and a lymphocytic pleocytosis; it is abnormal in 80–90% of cases and in some cases shows oligoclonal bands. The EEG shows diffuse or focal slowing in some 80% of patients. MRI may demonstrate infarcts or foci of oedema or ischaemia. MRI may also show gadolinium enhancement of the meninges. In a small proportion of cases findings on MRI resemble demyelinating disease. SPECT or PET may show focal areas of hypoperfusion.

Clearly, however, such investigations are insufficient for diagnosis or for excluding the condition, and when suspected angiography will always be required. This shows diffuse or localised changes in large and small arteries, with irregularities, beading and aneurysmal formation. If findings on cerebral angiography are to be relied on as evidence of vasculitis, then they need to be reasonably secure. There are many causes of localised changes on angiography that mimic arteritis. Without biopsy-proven histological evidence of a vasculitis, it is probably unwise to rely on anything less than multiple-vessel involvement in multiple vascular territories as the standard for angiographic evidence of cerebral vasculitis. It has been suggested that cases diagnosed solely on angiographic findings may have a more benign course than those in whom there is biopsy-proven angiitis, but this has not been confirmed (Woolfenden *et al.* 1998). A case series of 16 such cases found 12 to have headache, seven seizures, and stroke or TIA in eight (Abu-Shakra *et al.* 1994); two presented with impairment of consciousness, and a further three had cognitive impairment. One patient presented with psychosis, but it is not possible to determine if

this patient also had cognitive impairment or seizures; two patients were left with cognitive impairment at follow-up, on average a little over 2 years later. In both cases it was a multi-infarct dementia.

A wedge biopsy of cerebral cortex with overlying meninges is essential for the definitive diagnosis. If possible an area that shows changes on MRI is selected. Histology reveals an inflammatory process in the small and medium-sized arteries and arterioles of the brain parenchyma and leptomeninges; to a lesser extent venules and veins may be affected. Intimal thickening and fibrosis are accompanied by multinucleated giant cells and granuloma formation. Surrounding brain may show ischaemic changes including infarction, demyelination and axonal degeneration.

The diagnosis needs to be almost certain before embarking on the aggressive immunosuppressive treatment that is required, with its significant morbidity. Most authorities would therefore recommend a cerebral biopsy before starting treatment, even though this may be negative in one-quarter of cases, partly in order to rule out other conditions (Moore 1994). The prognosis was extremely poor before the advent of steroid medication. This, with cytotoxic agents such as cyclophosphamide and azathioprine, now brings hopeful prospects of treatment. In a series of 41 cases, followed up for on average 4 years, only 10% had died, and 80% were left with no, or only mild, disability (Calabrese 2001).

Polyarteritis nodosa

Polyarteritis nodosa, recently the subject of a useful review (Segelmark & Selga 2007), is characterised by involvement of many systems of the body and not infrequently the nervous system. It is quite rare, with a prevalence of about 30 per million. Many cases are associated with hepatitis B infection, and occasionally HIV or CMV or other virus infections. A hypersensitivity reaction is suspected in some cases. There may be a preceding history of streptococcal infection, and on rare occasions it may follow the administration of phenytoin, sulphonamides or other drugs.

A 1992 consensus conference on the nomenclature of vasculitic conditions restricted the definition of polyarteritis nodosa to a disease of small and medium-sized arteries (Jennette *et al.* 1994). Vasculitis involving smaller vessels, arterioles, capillaries and venules, often associated with glomerulonephritis and with positive ANCA antibodies and which would previously have been placed within the polyarteritis nodosa rubric, was now to be called microscopic polyangiitis.

The underlying pathology is a focal arteritis of small and medium-sized vessels. The larger arteries may also suffer due to involvement of their nutrient vessels. Highly characteristic focal dilatations are seen along affected vessels and whitish-grey nodules may be apparent macroscopically. A cellular reaction occurs at the site of the changes in and

around the vessel walls. Necrosis of the artery wall leads to rupture, and intimal proliferation causes thrombosis. Polyarteritis nodosa, along with Wegener's granulomatosis and microscopic polyangiitis, is one of the systemic necrotising vasculitides.

The onset is usually in middle age but the range is wide. Males and females are equally affected. The disorder may declare itself abruptly or insidiously, and tends to run a sub-acute or chronic course with relapses and remissions. Most patients have symptoms such as headache, malaise, weakness and a low-grade intermittent fever at onset. Weight loss may be profound and multisystem involvement is usually soon apparent. Renal insufficiency leads to severe hypertension in a high proportion of cases, and crises of abdominal pain result from infarctions in the mesenteric vessels and their tributaries. Gastrointestinal and renal involvement has a significant deleterious effect on prognosis. Arthritis and myositis are common. Pleuritic pain and pneumonitis may develop, and cardiac involvement leads to myocardial infarction, congestive cardiac failure and pericarditis. Skin lesions include livedo reticularis, purpura, ecchymoses, subcutaneous nodules, necrotic ulcers and superficial gangrene. In addition to hypertensive retinopathy, the eyes may show evidence of scleritis, keratitis, choroiditis, retinal artery occlusion or optic atrophy.

Laboratory investigations usually disclose anaemia, raised ESR, and reversal of the albumin-globulin ratio. However, there are no specific laboratory tests for the disorder. Leucocytosis is common, sometimes with eosinophilia. Most cases show uraemia, albuminuria and abnormal sediment in the urine. Chest radiography may show pulmonary infiltration or a pleural reaction. The CSF is sometimes under increased pressure, with elevation of protein, pleocytosis or xanthochromia. Arteriography via the aorta may reveal a diagnostic picture by way of multiple small aneurysms, focal dilatations, or infarcted areas in the kidneys or other abdominal organs. Biopsies from skin, liver, kidney or small nerves serve to confirm the diagnosis.

The disease formerly carried an extremely poor prognosis, death usually being attributable to renal failure or to coronary, mesenteric or cerebral infarction. Treatment with steroids and immunosuppressive drugs, usually in combination with one another, now offers hope of delaying or even halting progression. Hypertension warrants vigorous management and anticoagulants may be indicated.

Nervous system involvement

Peripheral neuropathy is the most frequent neurological finding and will be found in 70% of cases. The nerves suffer via their nutrient arteries, leading to multiple infarctions along their course. The result is usually a mononeuropathy or mononeuritis multiplex, with paraesthesiae, weakness and wasting. A symmetrical polyneuropathy is less common.

Cerebral manifestations appear in up to half of cases eventually, but usually in the later part of the illness (Moore 1994). A diffuse encephalopathic-like illness with cognitive impairment or seizures may be seen, perhaps more frequently in those with small artery involvement. In contrast, disease affecting the medium-sized arteries is more likely to present with intracerebral haemorrhage or subarachnoid haemorrhage or stroke-like episodes. Cranial nerve lesions are common, causing blurring of vision, vertigo, tinnitus and disorders of external ocular movement. Occasionally, a local mass of brain necrosis may simulate a tumour. Headache is common, sometimes attributable to hypertension and sometimes to arachnoiditis at the base of the brain. Epileptic seizures may result from uraemia, hypertension, diffuse encephalopathy or focal lesions in the brain.

Mental changes can figure prominently and occurred in 26 of 114 cases from the Mayo Clinic (Ford & Siekert 1965). The usual picture was of confusion and disorientation, sometimes with visual hallucinations and delusions. Delirium, 'mania' and paranoia were seen occasionally. Forgetfulness was noted in many patients, and seven showed marked intellectual deterioration. Eight showed a fluctuating impairment of consciousness varying from somnolence to coma.

Occasional cases are reported in which polyarteritis nodosa appears to be largely confined to the nervous system. MacKay *et al.* (1950) described a patient who for 2 years showed intermittent diplopia, hemiparesis and cranial nerve disorders accompanied by a low pyrexia, then developed depression and progressive dementia leading to death over several months. At post-mortem the typical changes of polyarteritis nodosa were largely confined to the brain and cord.

Primary small-vessel vasculitides

Wegener's granulomatosis, microscopic polyangiitis and Churg-Strauss syndrome all affect small vessels and are all associated with ANCA. Inflammation and fibrinoid necrosis of small-vessel walls (arterioles, capillaries or venules), with few or no immune deposits, is characteristic of each of these conditions. They are all relatively rare. The majority of patients will have general constitutional symptoms at presentation, for example a flu-like illness or generalised malaise. Involvement of the upper and lower respiratory tract is common. The granulomas of Wegener's granulomatosis commonly affect the ear, nose and throat, whereas Churg-Strauss syndrome typically presents with asthma; an eosinophilic vasculitis particularly involving the lungs is characteristic. On the other hand, renal involvement is also frequently seen and this is particularly common in microscopic polyangiitis, which may be associated with a rapidly progressive glomerulonephritis (Guillevin *et al.* 1999). Other organs that may be affected include skin, liver and heart.

ANCA may be detected using indirect immunofluorescence with ethanol-fixed human neutrophils as substrate.

Using this method it is possible to distinguish two patterns of immunofluorescence as ANCAs bind to their target: a granular cytoplasmic pattern (c-ANCA) and a perinuclear pattern (p-ANCA). The c-ANCA pattern tends to be associated with antibodies directed against proteinase 3, and this is what is generally found in Wegener's granulomatosis. However, there are reports of ANCAs against myeloperoxidase also producing the c-ANCA pattern, and this is found in Churg–Strauss syndrome. ANCAs against myeloperoxidase usually produce the p-ANCA pattern, and this is typically seen in microscopic polyangiitis. Patients with small-vessel vasculitis who are p-ANCA positive have the lowest risk of relapse (Pavone *et al.* 2006). There is reasonably good evidence that ANCAs have a pathogenic role in these conditions by activating neutrophils and by binding to a target antigen in the endothelium of the vessel to cause cell damage (Preston *et al.* 2002). In Wegener's granulomatosis, a rise in ANCA has shown to predict relapse of the disease (Slot & Tervaert 2004).

About one-quarter of cases, particularly those with Churg–Strauss syndrome, will have a neuropathy. Cerebral involvement is relatively uncommon, with perhaps only 1 in 20 affected (Pavone *et al.* 2006), although the figures may be higher for Wegener's granulomatosis.

Wegener's granulomatosis is characterised by necrotising granulomas in the upper and lower respiratory tract with a systemic necrotising vasculitis (Slot & Tervaert 2004). ANCAs are detected in the majority of patients (see above). Damage to the nasal septum may cause a saddle deformity of the nose when the cartilage supporting the bridge of the nose collapses. Between 10% and 20% of cases develop a neuropathy, the commonest being mononeuritis multiplex followed by a symmetrical distal neuropathy. Neurological involvement may also be a consequence of invasion of the base of the skull by large granulomas arising from nasal or paranasal sites. These may for example directly penetrate the orbits or intracranial cavity, or involve major arteries supplying the brain or cranial nerves. Less than 10% of cases will have a cerebral vasculitis, often with intracerebral or subarachnoid haemorrhage (Siva 2001).

A recent case series describes six cases with CNS involvement from a database of 80 cases of Wegener's granulomatosis (Seror *et al.* 2006). Two had a pachymeningitis, presenting with headaches: in one case the meningitis affected the falx causing an obstructive hydrocephalus, and in the other a diffuse meningitis was associated with seizures and behavioural change. In three cases the pituitary was affected; in one of these there had been a previous central retinal artery occlusion and a TIA involving the middle cerebral artery some years before, suggestive of cerebral vasculitis. One case had a typical picture of cerebral vasculitis with an intracerebellar haemorrhage followed by T2-enhancing lesions in the cerebrum. The subsequent review of the literature suggests

three clinical patterns of cerebral Wegener's granulomatosis: a chronic hypertrophic pachymeningitis (Jinnah *et al.* 1997), pituitary gland involvement, and cerebral vasculitis.

Untreated the prognosis for Wegener's granulomatosis is poor, with 1-year mortality of 80%, but with treatment three-quarters of patients will survive 5 years. Treatment generally relies on achieving remission with a combination of steroids and cyclophosphamide. Because cyclophosphamide is so toxic, RCTs have explored the consequences of replacing cyclophosphamide, once remission has been achieved, with a less toxic immunosuppressant. These have shown that it is safe to change to azathioprine or methotrexate for long-term maintenance therapy (Hellmich *et al.* 2006).

Giant-cell arteritis (temporal arteritis)

Giant-cell arteritis is a disease of large arteries and a disease of later years, rarely appearing before 60 years of age and being commonest in those aged 75–85 years (Weyand & Goronzy 2003). In North America and Europe it is the most common of the systemic vasculitides, with an incidence of the order of 100 per million per year (Siva 2001); it is much less common in east Asia. It is a disease of the aorta and its branches, but is particularly likely to affect the extracranial branches of the carotid artery. Of these the temporal arteries are most commonly affected, hence the alternative name temporal arteritis. Arteries show a subacute inflammatory reaction with necrosis, granulation and giant-cell formation. CD4⁺ T cells play a primary role in the pathogenesis. They penetrate the endothelium of the vasa vasorum, not the main vessel wall, and with the help of antigen-presenting cells then cause inflammation across the width of the arterial wall. Intimal proliferation may lead to thrombosis and occlusion. The ciliary arteries, which supply the optic nerve and disc, are involved in about 30% of cases. The aorta and its major branches are too large to occlude and instead damage to the vessel wall may produce dissection, rupture or aneurysmal dilatation. The disease is related to polymyalgia rheumatica and the two may occur together.

Clinically, there is often a prodromal phase of vague malaise with muscle and joint pains lasting for several weeks or months. A low pyrexia may develop and weight loss and depression may be marked. Characteristic headache then appears, sometimes abruptly, situated principally over the affected vessels in the temporal region. The temporal arteries may be palpable and exquisitely tender. Suffering is usually intense, with throbbing or lancinating pain and severe insomnia. Jaw claudication, with pain on chewing, is also characteristic.

The acute stage lasts for a week or two but tenderness may persist rather longer. At any time in the early days or weeks the serious complication of ciliary artery obstruction may follow, leading to impairment or loss of vision in one or both eyes, hence the importance of prompt diagnosis and treat-

ment. Ophthalmoplegias may also occur. The systemic disturbance continues throughout the stage of headache and visual complications, and may last for many months more. Peripheral neuropathy and muscle pain and wasting may occur. Infarctions can follow from involvement of the carotid or vertebral vessels. McCormick and Neuberger (1958) describe the brain lesions that may be observed at post-mortem, including involvement of small intracerebral vessels by giant-cell arteritis.

Mental disturbances sometimes feature prominently during the illness, with confusion, delirium, memory impairment and drowsiness proceeding to coma (Cloake 1951). Vereker (1952) described examples in the literature with restlessness, disorientation, severe memory difficulties and episodes of delirium, often with abrupt resolution after several weeks. Coma is a serious development, but patients can recover after several days. Vereker also stressed the frequency of severe depression in the disease, and considered that in many examples it was attributable to cerebral arterial disease rather than being secondary to the headache. Russell (1959) found that 7 of 35 patients were depressed and four were confused during the stage of headache.

The ESR is greatly raised and there may be a leucocytosis. However, in about 10% of cases the ESR may be normal in the early stages (Russell & Graham 1988). Biopsy of an inflamed artery serves to confirm the diagnosis. Steroids meet with dramatic success in treatment and must not be delayed. They are given in high dosage initially then reduced after 1–2 weeks to maintenance levels, which are continued for 6–12 months or sometimes indefinitely. Mason and Walport (1992) discuss the regimens involved. Anticoagulants may also be indicated in the acute stages. Giant-cell arteritis is a self-limiting disease so that once the acute phase is treated the illness usually becomes inactive within a few months to a year or two.

Takayasu's arteritis, pulseless disease, is also a disease of large vessels, particularly the aorta and its main branches and is found mainly in young women. Distal pulses are commonly absent. The disease may lead a fairly chronic course. Being much more common in Japan and eastern Asia, it has the opposite geographical distribution to giant-cell arteritis. Neurological sequelae, stroke or TIA, are not very common though headache is found in about half of cases.

Other conditions associated with vasculitis

Susac's syndrome consists of a triad of microangiopathy of the brain and retina with hearing loss; it is predominantly found in young women (Susac 1994) and is of uncertain aetiology. Headache is a common presenting symptom. The encephalopathy may be acute or insidious and several cases show insidious development of personality change associated with cognitive impairment. There is therefore the potential for such cases to present to a psychiatrist.

Thromboangiitis obliterans is virtually confined to male smokers, presenting usually between 25 and 40 years of age. The pathology is characterised by highly cellular and inflammatory occlusive thrombus with relative sparing of the blood vessel wall (Olin & Shih 2006). The medium-sized vessels of the legs are predominantly affected. Anti-endothelial cell antibodies may be pathogenic. A relapsing/remitting course is characteristic, affecting short segments of the vessels at a time so that lesions in all stages of activity are found at different sites. The common presentation is with intermittent claudication, leading eventually to gangrene of the toes. Superficial venous thromboses frequently occur. The affected limb is pulseless, cyanosed and cold. Nocturnal pain is typically relieved by hanging the leg downwards out of bed.

Cerebral involvement is rare but well attested, usually only when the peripheral disease is well established, though in occasional cases is the presenting feature. The possibility of the disease should therefore be borne in mind when young adult males develop cerebrovascular symptoms, especially in the absence of hypertension. The vessels principally affected are the internal carotid and anterior and middle cerebral arteries (Cloake 1951). Infarctions follow in the corresponding territories. In the early stages the deficits may be slight and transient, suggesting that they are due to episodes of spasm or emboli. Epileptic seizures are common and headache of migrainous type may occur. Later dementia can be profound with an end-state similar to that of multi-infarct dementia.

Polycythaemia rubra vera

Polycythaemia, one of the myeloproliferative disorders, exhibits an increase in red cell mass and usually an excess of white blood corpuscles and platelets as well. It presents mainly in middle or later life, and with a slight male preponderance. Sometimes it declares itself insidiously, or it may present with acute complications such as cerebrovascular accident or major thrombotic episode (Weatherall 1996). Patients may experience angina or claudication, or suffer recurrent emboli or venous thromboses. Complaints of pruritus are common. The facies is typically plethoric with injected conjunctivae, and splenomegaly and hepatomegaly are often present.

Neuropsychiatric features can be prominent and have been reported in half to three-quarters of cases (Silverstein *et al.* 1962). Impairment of the cerebral circulation leads to headache, impaired concentration, dizziness, vertigo and visual blurring. Episodes of confusion may progress to dementia. The increased blood viscosity predisposes to TIAs and cerebral infarctions. Murray and Hodgson (1991) reported a patient who developed a severe depressive illness with psychotic features after a series of TIAs, ultimately with good resolution after electroconvulsive treatment. Mania after an episode of delirium has also been reported (Chawla

& Lindesay 1993). Other cerebral symptoms occasionally include chorea, narcolepsy and seizures.

Willison *et al.* (1980) showed that patients with high-normal or above-normal haematocrit (range 0.46–0.77) were impaired on tests of alertness (tests of digit copying, counting backwards, letter cancellation and coding) compared with controls matched for age and occupation. After venesection the haematocrit fell from a mean of 0.54 to 0.45 and the test scores improved. The extent of improvement correlated significantly with increases in CBF as measured by ¹³³Xe inhalation. More recently, there has been a report of a 65-year-old man with a haematocrit of 60% who presented with confusional episodes and abulia, and severe executive impairments and moderate deficits in constructional praxis. There was a marked improvement in the confusional episodes following treatment of the polycythaemia, with some improvement on neuropsychological test performance (Di Pollina *et al.* 2000).

Cerebral venous sinus thrombosis

Largely because of CT and MRI, cerebral venous sinus thrombosis has changed in status from a rare fatal diagnosis only made at post-mortem to an illness that explains 1–2% of strokes (Renowden 2004). The outcome is very diverse and in general probably better than for arterial strokes. The onset is also more variable, with subacute or fluctuating presentations seen in two-thirds of cases (Masuhr *et al.* 2004). The commonest symptom is headache (80–90%), followed by focal neurological deficits, seizures or papilloedema (each in about 50%) (Bousser 2000). A good proportion, from 10% to 60% in different series, will show alteration of consciousness.

Four main patterns of presentation have been described (Bousser 2000):

- One pattern is typical of any stroke, with focal deficits, although epileptic seizures are very much more common than in arterial stroke.
- An isolated syndrome of raised intracranial pressure, with headaches, papilloedema and sometimes a sixth nerve palsy, often mimicking benign intracranial hypertension.
- Of most interest to the neuropsychiatrist is a subacute encephalopathy without localising signs but with delirium often accompanied by seizures.
- In the case of cavernous sinus thrombosis, a progressive, often painful, third or sixth nerve palsy.

Young women are at greatest risk, particularly if taking oral contraceptives or in the perinatal period. Other risk factors include head injury and infection, particularly of the middle ear. Cerebral venous sinus thrombosis has been reported as a rare complication of lumbar puncture. Systemic illness with cachexia, malignancies, heart failure or pulmonary embolism, and coagulation disorders are also on the long list of potential causes (Stam 2005). The commonest

sites of thrombosis are the superior sagittal sinus and the transverse sinus with more than one site usually affected (Stam 2005). The clinical picture depends somewhat on the site of thrombosis. Thrombosis of the cerebral veins tends to produce localised infarction, which is often haemorrhagic. Thrombosis of the major sinuses results in raised intracranial pressure, but without hydrocephalus.

CT and MRI are crucial for diagnosis (Masuhr *et al.* 2004). The first clue may be the pattern of ischaemia and infarction, which is often multifocal, haemorrhagic and does not match arterial territories. Evidence of thrombus in the sinuses may be easily missed; depending on the state of maturation it may be hypointense, isointense or hyperintense on CT or MRI. Over the first few days it may be isointense on T1 MRI sequences and hypointense on T2 sequences; then over the next few weeks hyperintense, firstly on T1 and then on T2 sequences. The pictures after a month can be quite variable depending on whether there has been recanalisation; in most cases the sinuses are isointense on T1 and hyperintense on T2 sequences. MRA allows the visualisation of the blocked veins and sinuses.

Treatment consists of the management of any precipitating factors and anticoagulation in selected cases. The mortality is of the order of 10–20%, and is worse in those presenting with a reduced conscious level. However, many make a full recovery and seem to be left with no sequelae.

There has been relatively little written about the long-term outcome in terms of cognitive and behavioural sequelae. In one study, based on an RCT of anticoagulant treatment in 59 patients, eight had died and four could not be followed up (de Bruijn *et al.* 2000); 47 patients were available for follow-up on average 18 months after the thrombosis. About one-third of patients showed impairments on cognitive testing. Nevertheless, all but three scored above 23 out of 30 on the MMSE. Worst performance was on the visuospatial maze test, with 15 of 46 patients scoring less than the 10th centile. In about 40–50% of patients their employment potential had been adversely affected by the thrombosis. In a cases series of 38 patients with thrombosis, 34 were available for assessment on average 3.5 years later (Buccino *et al.* 2003). Cognitive performance, as assessed using the MMSE, was normal in all except one who scored 21 and one 26 out of 30. Working memory impairments could be identified in six (18%). Depression, with a BDI of greater or equal to 10 was also found in six patients, but in no case did the BDI exceed 13. These two studies suggest that most patients make a good recovery after cerebral venous sinus thrombosis.

Alzheimer's Disease and Other Dementias (Including Pseudodementias)

Simon Lovestone

Institute of Psychiatry, King's College, London

Dementia is described in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-IV as a disorder with memory impairment and at least one other symptom from aphasia, apraxia, agnosia or disturbances in executive functioning accompanied by impairment in social and occupational function. The decline must represent a decline from a previously higher level of functioning. The causes are many and may be both cerebral and extracerebral, but must be distinguished from delirium. Prominent among them are certain intrinsic degenerative diseases of the brain occurring in middle or late life. These, the so-called primary dementias, are the subject of this chapter. Later in the chapter the concept of mild cognitive impairment, an intermediate state and in some people, but not all, a prodrome of dementia, is discussed.

By far the commonest of the primary dementias of late life is Alzheimer's disease (AD), chiefly by virtue of its sharply rising incidence with age. However, it is also true that AD is the commonest of the early-onset (previously called pre-senile) dementias, namely those with onset before age 65 years, although the relative proportions are less marked. Next in frequency are the vascular dementias, previously called 'multi-infarct' or 'arteriosclerotic' dementia, both in the late and early-onset age ranges. An interesting question is whether vascular dementia is strictly speaking a secondary rather than a primary degenerative brain process: in other words, does all the neurodegeneration of vascular dementia arise from simple loss of vascular supply to neurones (strictly a secondary dementia) or does a local and relative anoxia induce or enhance a complex neurodegenerative process (making it a primary dementia)? While this of some considerable interest in terms of pathophysiology, vascular dementia has traditionally been considered with the primary dementias. Dementia with Lewy bodies (DLB) is in most series of post-mortem and clinical prevalence studies the third most common dementia. Pick's disease, other frontal

dementias, Huntington's disease and the prion disorders, including Creutzfeldt-Jakob disease (CJD), constitute the best known of the remaining primary dementias and are all much less common. When the distinctive pathologies of the above conditions fail to be revealed at post-mortem in a patient with a primary dementing illness, it is usual to speak of a 'simple' or 'non-specific' primary dementia, although in the context of detailed neuropathology this is a vanishing and rare event. Rather more common is the presence of large amounts of AD pathology in people without dementia (MRC CFAS 2001).

An alternative approach to classification is emerging from neuropathological studies. As discussed below, one of the key neuropathological lesions of AD is the neurofibrillary tangle, which is composed of aggregates of tau protein, a protein that normally functions to stabilise microtubules in axons. Other conditions also have aggregates of tau protein, including progressive supranuclear palsy (PSP), corticobasal degeneration and some of the frontotemporal dementias (FTDs). As these disorders have some common pathologies and presumably therefore common mechanisms, it has been proposed that they be considered together as the 'tauopathies' (Lee *et al.* 2001). In contrast, other disorders, including DLB, Parkinson's disease and multisystem atrophy, feature aggregations of a protein, synuclein, in Lewy bodies and other lesions. These disorders have been called the 'synucleinopathies' (Duda *et al.* 2000), in contrast again to the 'amyloidopathies' that encompass the prion disorders such as CJD, some of the rarer dementias such as familial British or Danish dementia and AD. Herein lies one of the flaws of such a classification, as AD is both a tauopathy and an amyloidopathy, and some cases, including early-onset autosomal dominant AD, have Lewy bodies also and are therefore synucleinopathies. There is probably more overlap than clear distinction between these different pathologies. Nonetheless, the classification is important, as it is the first attempt

to classify the primary dementias according to mechanism and pathology rather than by clinical features. It draws attention to the fact that very different clinical pictures can emerge as a consequence of very similar pathological processes, the different clinical picture reflecting less pathology than the neuroanatomical locations of the lesions (compare, for example, the synucleinopathies Parkinson's disease and DLB and the tauopathies PSP and FTD) and possibly the relative admixture of lesions. Even more importantly, if there are common mechanisms, then it suggests the possibilities of common therapies. For example, a disease-modifying therapy reducing the formation of tau aggregates might conceivably be as useful in PSP as in AD. For the time being, however, this neuropathological and putative mechanistic formulation of classification remains to be proven and the conventional symptom-based classification has more clinical utility, not least in predicting outcome.

The general clinical picture is similar in all common dementias: a progressive disintegration of intellect, memory and personality accompanied by loss of functional abilities and behavioural disturbances. The different conditions are distinguished to some extent by the rapidity of their course or by associated symptoms and signs, as described when the individual disorders are considered in turn. Differential diagnosis has improved and in most cases the disorders can be distinguished with some considerable degree of accuracy in life, although a definitive diagnosis is revealed only by careful post-mortem examination of the brain, and even then a measure of uncertainty can remain in some cases. The relationship between the three commonest dementias, particularly AD, vascular dementias and DLB, is complex and these forms frequently coexist (Holmes *et al.* 1999; MRC CFAS 2001). The contribution of the various pathological events associated with these diagnoses to the actual symptoms of dementia is often unclear in a single case or indeed overall.

It is as true today as it was in the previous editions of this book that in terms of overall outcome these diseases share a uniformly poor long-term prognosis although symptomatic treatments have improved. Given the huge advances in understanding the pathophysiology of the conditions and the strides being taken to develop disease-modifying drugs, it is to be hoped that this will, in the foreseeable future, no longer be the case. However, even without disease-modifying or primary preventive strategies, it is no longer the chief aim in diagnostic practice to distinguish them from the secondary dementias, i.e. to search for the other causes of chronic organic reactions that may have some therapeutic issue. Indeed the frequency of these 'reversible' dementias, previously thought to be a major diagnostic dilemma, is very low. In a meta-analysis of studies including nearly 6000 patients with dementia, only 9% were found to be potentially reversible and only 0.6% actually reversed (Clarfield 2003). Although detection of this "less than 1% of all dementias" is important, the main aim of diagnostic practice now is to determine if it is appropriate to prescribe one of the growing

numbers of symptomatic treatments; to consider, in the case of vascular dementia, the role of secondary preventive measures; and in all the dementias to offer sufferers and families advice, support and, where appropriate, prognostic information. Diagnosis or detection of behavioural disturbance is also a task of immense importance for the clinician and in many but not all cases a combination of behavioural, environmental and pharmacological approaches can manage even the most disturbed of patients.

Alzheimer's disease

Dementia setting in after the age of 65 (late-onset, previously called senile, dementia) has usually been considered separately from that occurring in younger patients. The organisation of clinical services for the elderly, and the development of the specialities of geriatrics and psychogeriatrics or old age psychiatry, has served to reinforce the practice. While this has had undoubted benefits in terms of development of clinical services for the elderly and indeed for professional consolidation of the various clinical disciplines, it has had the unfortunate consequence that late-onset dementia has tended to acquire nosological status as a separate and distinct entity in clinical and even in some research writing. In fact the dementias of the elderly can have several causes, as at any other age, and with advancing age multiple causes will often be operative together.

The most common pathology displayed at post-mortem in elderly demented patients is closely similar to, if not identical with, that of AD in younger persons. Historically, this was labelled 'parenchymatous senile dementia' and then 'senile dementia of the Alzheimer type' (SDAT) but now simply AD. The change in terminology reflects the increasing body of evidence that the conditions are likely to be identical whether setting in before or after age 65 years. The distinction between early onset and late onset, with age 65 as the cut-off, has more relevance to social factors such as retirement than to biology. In many respects it has added confusion to an already complicated field. A more meaningful distinction might be between very early-onset AD occurring before age 50–55, very late-onset AD occurring after age 80–85 and the majority of AD occurring between these age ranges. There is very good evidence of a genetic distinction between these categories, with almost all autosomal dominant AD occurring before age 55 and with apolipoprotein E gene (*APOE*) variation being a susceptibility factor for later-onset AD but with this gene having less importance in the very elderly. Despite this clear evidence of genetic aetiological differences between very early-onset, late-onset and very late-onset AD, the neuropathological features are very similar and there is no evidence to suggest differences in the pathological mechanisms leading to neurodegeneration. Therefore we consider all forms of AD together and do not adhere to the convention of distinguishing 'presenile' from 'senile' AD despite the precedents of both Alzheimer and Lishman.

Community, clinic-based and neuropathological studies all concur that AD is the commonest of the dementias, occurring in up to two-thirds of all dementias (Polvikoski *et al.* 2001; Stevens *et al.* 2002). A second large group consists of the vascular dementias, whereas an admixture of these two common forms of pathology determines a third. Considerable evidence suggests that these mixed dementia may in fact be the predominant neuropathological presentation, with increasing acknowledgement that this may not be only a chance occurrence of two common conditions. DLB occurs more frequently in some series than others, perhaps reflecting post-mortem diagnostic practices as well as clinical factors, but in any case is an important category of patients coming to post-mortem with dementia. The relatively small remainder of cases is likely to show a range of other causative pathologies, or the brain may be normal apart from the changes expected with age.

In this chapter, the sections on AD, vascular dementia and DLB describe the clinical picture and underlying pathology of these conditions in some detail.

Prevalence and incidence

As a consequence of increasing longevity in the population, the prevalence of dementia has risen and continues to rise alarmingly. It was estimated that in 1997 there were approximately 2.3 million persons with dementia in the USA, with a further 360 000 new cases arising annually (Brookmeyer *et al.* 1998). It is estimated that in 2008 there were approximately 5.2 million persons with dementia in the USA, with over 410 000 new cases arising annually (Alzheimer's Association 2008, Alzheimer's Disease Facts and figures www.alz.org/national/documents/report_alzfactsfigures2008.pdf). In the UK there are an estimated 750 000 people with dementia and, globally, over 24 million people, with these prevalence figures forecast to rise to over 80 million by 2040 (Ferri *et al.* 2005). Altogether dementia now ranks as the third most common cause of death in the USA, on a par with cardiovascular disease (Ewbank 1999).

The implications of a problem on such a scale for the cost and provision of care are clearly enormous. Kay *et al.* (1970) were able to show that admission rates to hospital in 1970 for the elderly demented exceeded the rates for all other psychoses combined, likewise that their demands on hospital and residential facilities outstripped those due to all other forms of disability in old age. Not surprisingly the costs, in particular to health services but also to carers and families, is simply huge, being estimated at between £7 billion and £14 billion in the UK, compared with costs of £3 billion for stroke, £4 billion for heart disease and £1.6 billion for cancer (Lowin *et al.* 2001). These estimates include family and other non-service caregiving costs but even the direct costs to health services are considerable in AD, one estimate of direct Medicaid costs in the USA being \$14 492 per AD recipient (Martin *et al.* 2000). The costs of dementia rise with severity, one study from

Denmark for example showing that the costs of mild dementia were DKK93 000 rising to DKK206 000 for severe dementia (Andersen, C.K. *et al.* 1999). Most of the change in costs with severity result from decline in function rather than specifically cognition (Wolstenholme *et al.* 2002) as it is functional loss above all else that demands intervention both in the community and even more so in residential and nursing homes.

Yet even these statistics from diagnosed patients underestimate the size of the problem. The Newcastle upon Tyne survey of a random sample of people living at home, coupled with a census of institutions in the same area, disclosed that fewer than one-fifth of even the more severe cases were in hospitals or homes for the elderly (Kay *et al.* 1964). Only a proportion of dementia in the community is recognised by services, with general practitioners being aware of perhaps half to two-thirds of all dementia among their patients (O'Connor *et al.* 1988). Neuropathological studies of elderly people concur with these findings with, for example, the prevalence of neuropathological features sufficient to cause AD being twice as common as a clinical diagnosis of AD in a large prospectively examined community-based cohort (Polvikoski *et al.* 2001).

All epidemiological studies have shown that of the dementias, AD is the most common, although increasingly the contribution of multiple pathologies to the manifestation of dementia is recognised. The European Community Concerted Action on the Epidemiology and Prevention of Dementia Group (EURODEM) initiative is a collaboration between multiple epidemiological studies of dementia across Europe; in an analysis of six such studies, Rocca *et al.* (1991) found similar prevalence rates of AD in the different participating countries. Overall, European prevalence was 2% for the age group 30–59, rising exponentially with age to 11% in people aged 80–89 years. Some studies have found even higher prevalence rates: in a study of nearly 4000 persons in the USA, the prevalence was 3% in those aged 65–74 years, rising to 47% in those over 85 years old (Evans *et al.* 1989). Some of the differences reported between studies almost certainly reflect methodological differences (Jorm *et al.* 1987) but overall the rates are of the order of 5% for all those aged 65 years and older, doubling thereafter every 5 years to a total of 20–30% of all those aged over 85 years. Incidence figures reflect these high rates. In a UK study the incidence of AD in a community-based sample over the age of 75 years was 2.7 per 1000 person-years at risk, with the rates for men being twice those of women (Brayne *et al.* 1995).

Neuropathological studies concur with clinical studies that AD is the commonest of all dementias, occurring in approximately 60% of cases with dementia (MRC CFAS 2001). These figures are not substantially different from the seminal studies of Blessed, Tomlinson and Roth that mapped the late-onset dementias (Blessed *et al.* 1968; Tomlinson *et al.* 1970). However, in the MRC Cognitive Function in Ageing Study, a longitudinal examination of cognitive change in the

elderly in the community, it was clear that not only AD but cerebrovascular changes were common and the admixture of both pathologies was very frequent (MRC CFAS 2001). It is also clear that presence of pathology itself is not enough to induce dementia as one-third of people without dementia had similar amounts of pathology as those with dementia. This disparity between pathological load and cognition has been observed in other studies (Leaper *et al.* 2001; Meguro *et al.* 2001; Bigio *et al.* 2002; Riley *et al.* 2002). This remains something of a puzzle: perhaps some people are more vulnerable to a given amount of pathological insult because they have less of a quantity, loosely termed 'reserve'. What reserve might be is open to question. It might be that reserve is a physical attribute of the brain such as numbers of neurones or synapses or a functional, cognitive, attribute such as connectivity or plasticity. It might be inherited or arise as a consequence of environment. There is some evidence for both. Stern (2002) conceptualised these two components, cognition and brain, as active and passive elements of reserve. Alternatively, it might be that the neuropathological features of AD are only the tip of the iceberg and that cognitive impairment and dementia result from loss of neuronal function that is not apparent on post-mortem where only the insoluble, stable, gross pathological defects are present. This is not unlikely as there is some evidence that the earliest effects of pathological change in AD is loss of axonal transport, a process that would not necessarily be apparent at post-mortem.

Clinical features

The onset of AD is usually after the age of 40, although rare cases have been reported at younger ages. Given the exponential increase in incidence after age 75, the vast majority of people with AD are elderly, although early-onset AD remains an important condition both in terms of providing dementia services and in understanding the pathogenesis of the condition. At all ages females outnumber males by a ratio of 2 or 3:1, with the exception of the early-onset familial forms of the condition, which as an autosomal dominant inherited condition occurs equally in males and females.

For both early-onset and late-onset and familial and non-familial forms, the onset is usually insidious and can be dated only imprecisely. The slow development of the intellectual deterioration often allows the patient to preserve considerable social competence until the disease is well advanced. Insight is lost relatively early in the condition, something relatives sometimes consider a fortunate occurrence, but it is important to remember that often partial insight is retained in the early stages.

It remains true that the early stages are commonly overlooked by relatives and even by medical attendants, although this is more likely to be the case in late-onset than early-onset AD. Partly this is due to low expectations of the elderly but

partly also to a genuinely less intellectually challenging life for many people post retirement. Failing memory and lack of initiative and interest tend to be regarded by many, including family and friends, as no more than an accentuation of the normal processes of ageing and this shows little signs of changing. An exaggeration of such traits as obstinacy, egocentricity and rigid adherence to old habits may be viewed likewise. Moreover, old people may already have adopted a circumscribed routine within which cognitive failure is slow to be exposed.

While the onset of dementia is insidious, it not infrequently comes to attention as a result of some acute disturbance. An intercurrent illness may have taxed the reserves of the failing brain beyond their limit or resulted in an acute episode of delirium. Or a sudden change of environment or the loss of a partner may have abruptly revealed the inroads made by the disorder. Other cases come to notice as a result of the social disorganisation produced by the dementing process: the patient may wander away and get lost, become suddenly abusive on account of paranoid delusions or harm himself due to some clumsiness or accident.

Three main phases to the disease are commonly distinguished. The first, often lasting for 2 or 3 years, is characterised by failing memory, muddled inefficiency over the tasks of everyday life and spatial disorientation. The second stage brings more rapid progress of intellectual and personality deterioration and focal symptoms appear. An accent on the parietal lobes is common, with dysphasia, apraxia, agnosia and acalculia. The third or terminal stage consists of profound apathetic dementia in which the patient becomes bed-ridden and doubly incontinent. Gross neurological disability may sometimes develop, such as spastic hemiparesis or severe striatal rigidity and tremor. Forced grasping and groping may be seen, along with sucking reflexes. The frequency of epilepsy has sometimes been quoted as a distinctive feature of AD and a history of seizures was reported in 3% of one series (Burns *et al.* 1991a) and more than 20% in another (Volicer *et al.* 1995). Minor seizures may occur early in the disease, although grand mal fits appear to be mainly a late development. In the terminal phase of the disease, bodily wasting may be rapid despite adequate preservation of appetite. In a systematically assessed cohort of largely advanced dementia, the commonest neurological sign was a snout reflex, present in 41%, extrapyramidal signs were observed in 12% and myoclonus in 5% (Burns *et al.* 1991a).

Differences between early-onset and late-onset AD

There are few well-documented and consistent differences between early- and late-onset AD. This is complicated by the fact that true early-onset (i.e. before age 55 years) AD is not infrequently familial and there is some evidence for particular neuropathological patterns in some families and possibly clinical patterns too. However, the general clinical picture for early- and late-onset AD follows the same pattern of decline

except that the onset may be particularly hard to discern and parietal lobe symptomatology is less regularly conspicuous in the elderly. Among older patients it is possible that the disorder can sometimes follow a relatively protracted course as a result of more 'benign' development of pathological changes, and physical frailty and concomitant systemic illnesses are more likely to complicate late-onset than early-onset AD. Patients with early-onset AD are more likely to decline quicker (Lucca *et al.* 1993; O'Hara *et al.* 2002) and more likely to have difficulties with word comprehension and naming ability (Imamura *et al.* 1998), although clinically apparent speech impairments occur in both early- and late-onset AD (Cummings *et al.* 1985). There may be greater visuospatial deficits in people with early-onset AD (Fujimori *et al.* 1998). There are no neuropathological or neurochemical features exclusive to either early- or late-onset AD. For example, cerebrospinal fluid (CSF) measures of cholinesterase activity and choline showed no difference between early- and late-onset AD (Kumar *et al.* 1989). On balance, therefore, while there may be subtle neurocognitive differences and the general frailty of some people with late-onset AD may be reflected in the clinical presentation, the pattern of decline and the neuropathological substrates of that decline are remarkably similar no matter what the age of onset.

Symptoms in Alzheimer's disease

Cognitive impairment

The cognitive changes of dementia differ in kind and quantity from those experienced as a consequence of ageing. They are often considered as the four As: amnesia, aphasia (more correctly dysphasia in AD), apraxia (or dyspraxia) and agnosia.

Amnesia

Memory impairment is an invariable and early symptom of AD. Typically the loss is for recent events, with relative sparing of working memory in the very early stages and of remote memories even to moderate stages of disease. Recent memory function or recall is tested as part of the Mini-Mental State Examination (MMSE) (Folstein *et al.* 1975), and in the very early stages of disease the patient might typically be able to repeat three items (working memory) but fail to recall all three after only a few minutes. The rate of forgetting of new memories is greater in AD than in other groups with amnesias (Moss *et al.* 1986) as is the rate of storage into long-term memory (Petersen *et al.* 1994). However the rate of forgetting of fully stored memories may not be any lower than similarly aged people (Becker *et al.* 1987), suggesting that the primary neuropsychological deficit in AD is one of encoding and storing memories rather than failure to retrieve or to primary loss of memories.

As the disease process progresses, even more remote memories are lost and amnesia is manifested as episodic,

semantic and visuospatial deficits. Episodic memory is that for events and there is, as expected, a gradient for loss with more recent events being lost before more remote events. This may represent a combination both of greater rehearsal of older events and of a failure to store recent events effectively. Semantic memory is inexorably connected to, but distinct from, language: it is the knowledge and understanding of words, facts and concepts and in AD is relatively preserved early in the disease process but becomes compromised as the disease progresses. Semantic memory can be tested by word fluency (e.g. 'Name all the animals you can in one minute'). Visuospatial skills are addressed in the MMSE by copying of pentagons and are manifested clinically by becoming disorientated in strange environments, perhaps by wandering and by becoming lost even in a familiar environment.

Aphasias

Early in the disease process language loss may be hard to detect as the patient uses a variety of strategies to conceal this. However, carers and others in close contact with the patient will often comment upon it and many patients themselves find it a frustrating and difficult symptom. Nevertheless, the loss of speech often does not progress or not progress as profoundly or rapidly as in FTDs, which can proceed to mutism relatively early in the condition. Aphasias early in the disease process may be associated with more rapid decline (O'Hara *et al.* 2002). The earliest changes are word-finding difficulties and this can be tested for by asking the patient to name an increasingly complex set of items (e.g. jacket, sleeve, cuff, seam). The patient may try to compensate with circumlocutions and generic or indefinite terms. At this stage syntax may appear superficially intact but close analyses may reveal unfinished sentences, inappropriate usage of tense and other relatively minor errors. As the disease progresses, receptive difficulties become increasingly apparent and in the final stages of the disease speech becomes increasingly degraded with perseverations, echolalias, decreased fluency and non-speech verbalisations.

Apraxias

Difficulties with complex motor tasks not due to a primary motor deficit are a major determinant of the care needs of a person with dementia because they result in increasingly poor self-care and increasing risk of harm. In the early stages this may be elicited by asking the patient to enact a command (ideomotor apraxia) and in a more detailed and goal-orientated manner by a dressing or kitchen assessment often conducted by an occupational therapist.

Agnosia

The failure to correctly interpret a sensory input, or agnosia, is common in AD and particular attention is drawn to prosopagnosia and especially autoprospagnosia. This failure to recognise one's own face can be particularly disturbing and can cause diagnostic confusion to the unwary.

An elderly lady was referred as suffering from visual hallucinations. She reported seeing faces when out shopping leering at her from shop windows. A visit to her house revealed bathroom mirrors that had been taped up and covered in newspapers. On questioning she commented that the face she saw was always wearing the same hat as she commonly wore and it was easy to demonstrate the symptom by showing her a mirror. Interestingly she recognised that the face bore many similarities to her own but commented that it looked older than she did.

This symptom results, as in the case above, in the ‘mirror sign’ where patients interpret their reflection in the mirror as a stranger and may even be observed to converse with it.

Executive function

The ability to plan, to organise and to maintain attention are lost early and consistently in AD. However, of the various cognitive deficits it is probably the most taxing to assess, especially in someone showing amnesic and aphasic difficulties. The serial 7s of the MMSE is probably the most commonly assessed executive function, with the Stroop test or card-sorting test being used in more detailed assessments. Executive functioning is considered to be a primary frontal lobe function and relative sparing of memory with a predominance of executive function loss and speech deficits suggests a frontal lobe predominant dementia. Other tests of frontal lobe function can be usefully employed, including bedside tests of perseveration (e.g. copying hand sequences).

Sourander and Sjögren (1970) drew attention to the frequency of behavioural abnormalities suggestive of temporal lobe dysfunction in early-onset AD, particularly phenomena reminiscent of Klüver–Bucy syndrome in animals after bilateral temporal lobe excision. Late phenomena included strong tendencies to examine and touch objects with the mouth (hyperorality), and tendencies to be stimulus-bound to contact and touch every object in sight (hypermetamorphosis). Hyperphagia was often a terminal phenomenon, with indiscriminate eating of any material available. The emotional changes of apathy and dullness were similarly reminiscent of the pathological tameness of monkeys with Klüver–Bucy syndrome. Such manifestations were observed in over three-quarters of patients with AD, and in some of them the full gamut of phenomena was displayed. The human counterpart of Klüver–Bucy syndrome has been occasionally observed with other cerebral disorders such as arteriosclerosis, Pick’s disease and cerebral tumours, but Sourander and Sjögren considered that in most cases it formed an essential part of the symptomatology of AD. To some extent this was confirmed in late-onset AD by Burns *et al.* (1990a), who found features of Klüver–Bucy syndrome frequently in late-onset AD although the full syndrome only

rarely. The association with temporal lobe loss was also confirmed.

Functional impairment

Declining ability to perform everyday tasks (activities of daily living, ADL) is an invariable accompaniment to the cognitive loss in AD. Indeed deficits in ADL are an essential component of the DSM-IV diagnostic process for AD. ADL is often considered as basic (self-care) and instrumental and it is the latter that are lost first. Assessing ADL loss is important not only as this represents a core component of severity assessments but also because loss of function is an important predictor of institutionalisation (Riter & Fries 1992). Reisberg *et al.* (1986, 1989) have done much to describe the pattern of decline in function in AD and this has been encompassed in the Functional Assessment Staging (FAST) and Global Deterioration Scale (GDS) both of which use descriptions of functional loss to grade severity in AD (Reisberg *et al.* 1982; Reisberg 1988). Thus FAST stage 1 is a normal adult with no functional loss; stage 2, the patient might have some difficulty in finding personal belongings; stage 3, compatible with very early AD, the patient will have functional difficulties apparent only in demanding circumstances such as at work; stage 4, representing mild AD, the patient might need assistance with handling finances; stage 5, the patient could have difficulty in dressing as in moderate AD; stage 6, the patient would have loss of most basic ADL ability; and stage 7, the patient would be at the end stage of dementia where the patient would become bedbound. These seven broad stages have been expanded into substages in updates of FAST (Reisberg 1986).

Perhaps surprisingly there is only a modest correlation between the loss in cognition and the loss in function, and the MMSE is not a reliable predictor of the functional ability of any one individual, especially in the less impaired (Reed *et al.* 1989). Thus Teri *et al.* (1989) showed that age was a better predictor of functional loss than cognitive state. Functional loss must therefore be evaluated on an individual basis but in practice this can be difficult in the mildly affected. Instrumental functional abilities are highly gender, class and age-cohort specific. One patient reports making an error when using a power drill, another finds switching programs on the computer difficult and a third reports using a hot wash cycle for delicate woollens in the washing machine. All are real examples and your guesses as to patient characteristics are likely to be both correct and not prejudicial. While scales have been developed (see Burns *et al.* 2002) these tend to be most useful in the moderate stages of the condition. In practice in the clinic the question ‘Is there anything you used to do that you find difficult now?’ to both patient and informant is a good start. As the subject deteriorates, loss of function dictates much of the care needs and has important safety considerations and an occupational therapy assessment is invaluable in assessing function both in staged environ-

ments such as a mock-up kitchen and importantly in the patient's own home.

Behavioural and psychological symptoms

Alzheimer recognised the importance of non-cognitive symptoms, noting in his seminal case study that 'the first noticeable symptom of illness shown by this 51-year-old woman was suspiciousness of her husband. [At times] believing that people were out to murder her, [she] started to scream loudly. At times she . . . seems to have auditory hallucinations' (Alzheimer 1907; Jarvik & Greenson 1987). The many symptoms of AD, other than cognitive changes and functional losses, are now brought together under the rubric 'behavioural and psychological symptoms of dementia' (BPSD). These symptoms are common and core features of AD and not secondary or rare features. Broadly speaking, BPSD can be grouped together as psychotic, mood and activity related (Table 9.1). The prevalence is high but, as can be seen in the table, highly variable in different studies. Much of this variability results from different criteria adopted for symptoms, some studies counting symptoms of depression and others only major depression meeting DSM-IV criteria. Also the frequency varies according to the stage of the disease and few studies are truly prospective. Disease-lifetime prevalence of BPSD is very high indeed and few patients escape some symptoms. Some evidence suggests that certain behavioural symptoms occur together: Hope *et al.* (1997) found three distinct syndromes, overactivity, aggressive behaviour and psychosis, whereas in the Cache County study patients were grouped into those with psychotic symptoms, those with affective symptoms and those with no or only one symptom (Lyketsos *et al.* 2001).

Looking after people with dementia is difficult and looking after people with behavioural disturbance is harder. A con-

siderable body of work suggests that it is BPSD that impacts most on carers (Coen *et al.* 1997; Donaldson *et al.* 1998). Sleep disturbance is particularly difficult for carers: it saps energy and is difficult to manage. BPSD are also a major determinant of entry into institutional care (Cohen *et al.* 1993; Vernooij-Dassen *et al.* 1997). As this has become increasingly recognised, BPSD have become a target for therapy, both pharmacological and behavioural.

Psychotic symptoms

Depending partly on how it is defined, some form of psychosis occurs in up to one-third of people with AD. There is some evidence that those with psychotic features tend to decline quicker than those without (Drevets & Rubin 1989; Rosen & Zubenko 1991) but are not at greater risk of early mortality (Stern *et al.* 1994; Samson *et al.* 1996). There is no consistency in the literature regarding whether psychoses occur most frequently early or late in the condition but there is an inherent confounder in these studies in that it is easier to ascertain psychosis in the early stages where individuals retain language and can make their experiences understood. Psychosis must be a supremely distressing symptom and it is no surprise to find a number of studies showing an association between psychosis and aggression (Deutsch *et al.* 1991; Aarsland *et al.* 1996; Gormley *et al.* 1998). However, psychotic features are also associated with depression, suggesting that perhaps there is a common mechanism to behavioural disturbance in AD (Bassiony *et al.* 2002).

Delusions are the most common symptom and have a distinct flavour distinguishing them from the delusions of mood disorders or schizophrenia. Most common of all are delusions of theft, sometimes accompanied by a relatively complex explanation as to how the object was stolen.

Table 9.1 Frequency of behavioural and psychological symptoms in Alzheimer's disease.

Symptoms	Prevalence (%) (approximate)	Example references
<i>Psychotic</i>		
Hallucinations	20–30	Teri <i>et al.</i> (1988), Deutsch <i>et al.</i> (1991)
Paranoid or delusional ideation	20–30	Drevets & Rubin (1989), Deutsch <i>et al.</i> (1991)
Misidentification syndromes	10–20	Reisberg <i>et al.</i> (1987), Deutsch <i>et al.</i> (1991)
<i>Mood</i>		
Depression	10–25	Greenwald <i>et al.</i> (1989), Rovner <i>et al.</i> (1989), Sultzer <i>et al.</i> (1992)
Mania	<5	Burns <i>et al.</i> (1990b), Lyketsos <i>et al.</i> (1995)
Anxiety	>50	Jost & Grossberg (1996), Teri <i>et al.</i> (1999)
<i>Activity</i>		
Apathy	15–40	Starkstein <i>et al.</i> (2001), Lyketsos <i>et al.</i> (2002)
Agitation	30–70	Tractenberg <i>et al.</i> (2003b), McCurry <i>et al.</i> (2004)
Wandering	15–40	Klein <i>et al.</i> (1999), Holtzer <i>et al.</i> (2003)
Aggression	20–40	Deutsch <i>et al.</i> (1991), Eastley & Wilcock (1997)
Circadian rhythm disturbance	30–80	Tractenberg <i>et al.</i> (2003a), McCurry <i>et al.</i> (2004)

An elderly woman with AD became increasingly in need of social services as she no longer allowed her daughter into her flat. When her daughter visited she was treated with suspicion and at times shouted at and on one occasion had a stick raised to her. Needless to say this was distressing to the daughter and made caring for the patient difficult. Eventually the patient confessed to a community nurse that she believed that the daughter was systematically robbing her of her life savings and as evidence demonstrated that she did not know where her purse was. She claimed her daughter had taken it and when it was pointed out that the daughter had not been allowed to visit said the daughter came into the flat at night, climbing through the windows.

Although true delusions, the delusions of AD are usually secondary in that often the primary psychopathological event is amnesia. In the case above the primary event appeared to be mislaying a purse, which led to the secondary delusion of theft, a belief which was held with unusual conviction, was not amenable to reason and was manifestly erroneous (Sims 1988).

Hallucinations in AD are also distinct from those in other, primary, psychoses. Visual are the most common followed by auditory and then olfactory and tactile. Visual hallucinations may be complex, often of small animals or people and may be unaccompanied by fear or anxiety. Typically they are silent and sometimes the person with dementia has some insight, recognising that these experiences are in some way different from normal perceptions. Visual hallucinations form the most distinct of the clinical triad that make the diagnosis of DLB but are not in themselves pathognomonic, since visual hallucinations also occur in people with classical AD pathology.

Misidentification syndromes are distinct from prosopagnosias: in a true misidentification syndrome the person with AD is able to identify the face correctly (in person or from a photograph) but believes that an impostor has 'taken over' or replaced the other. One very common manifestation of a misidentification syndrome is where family members are mistaken for one another. Many children of people with AD become accustomed to being addressed as if they were a sibling or spouse of the patient. It can be difficult to distinguish a true misidentification event from a word-finding difficulty for names.

There have been considerable attempts to understand the underlying pathophysiology of psychosis in AD, partly for its own sake but also partly because it might contribute to the search for understanding of primary psychoses. Functional neuroimaging suggests relative hypoperfusion of dorsolateral frontal and dorsolateral parietal regions in AD with psychosis compared with AD without psychosis (Kotrla *et al.* 1995; Mega *et al.* 2000) and this may be in line with Cummings

(1985) who postulated disruptions to the corticolimbic systems as being common to many 'organic' delusions. It may be the relative activity of cholinergic and dopaminergic pathways in this system that is important and using receptor binding a moderate increase in D₃ binding in AD with psychosis was found in one post-mortem study (Sweet *et al.* 2001), although others failed to find a change in dopamine activity (Bierer *et al.* 1993) or a relative decrease in serotonergic activity (Zubenko *et al.* 1991).

Surprisingly, perhaps, as it is the exception rather than the rule, it is genetic studies that have been most replicable. Thus sib-pairs have been shown to share non-cognitive features more often than expected by chance alone in replicated studies (Tunstall *et al.* 2000; Sweet *et al.* 2002), and using a linkage approach susceptibility regions for AD plus psychosis have been found on regions of the genome also associated with schizophrenia (Bacanu *et al.* 2002). Given the neurophysiological evidence for dopamine and serotonin alterations in AD with psychosis, this was the obvious starting point for candidate association studies and it seems that variation in serotonin receptors is associated with risk of hallucinations (Holmes *et al.* 1998; Nacmias *et al.* 2001; Rocchi *et al.* 2003) and variation in dopamine receptors with risk of delusions (Sweet *et al.* 1998; Holmes *et al.* 2001).

Affective symptoms

Depression in particular has a complicated relationship with AD. Depression is a common non-cognitive feature, can be a precursor or prodromal syndrome (Schweitzer *et al.* 2002) and can be confused with dementia (pseudodementia). Of these, perhaps the most important is the first in that it is treatable and yet too often not treated. The prevalence of depression in AD differs widely according to the research methodology used and depends to a large degree on what is meant by depression. Major depressive episodes occur in approximately 10% or less of patients but minor depressive episodes occur in up to 30% and perhaps a majority of patients suffer some symptoms of depression (Reifler *et al.* 1986; Weiner *et al.* 1994, 2002; Migliorelli *et al.* 1995; Ballard *et al.* 1996; Brodaty & Luscombe 1996; Jost & Grossberg 1996; Li *et al.* 2001). Another difficulty is determining depression in different stages of dementia. Although scales for assessing depression in dementia are available (e.g. Cornell Scale for Depression in Dementia; Alexopoulos *et al.* 1988), assessing more subtle signs of depression becomes harder as the primary condition progresses.

It has been reported that there is a preferential loss of neurones in the *locus coeruleus* and possibly the dorsal raphe nucleus in AD with depression (Zweig *et al.* 1988; Förstl *et al.* 1992), suggesting that loss of noradrenergic or serotonergic function may be important. However, most neuropathological association studies are fraught with difficulties: the time between assessment and post-mortem may be considerable, the assessment of clinical features may have been only at one

time point, and the numbers are frequently small. Although the association of loss of particular monoaminergic neurotransmitter neurones and depression in AD is intellectually satisfying, it remains to be fully replicated and some studies fail to find such an association (Hoogendijk *et al.* 1999).

Family studies show little linkage between late-onset depression (LOD) and AD, suggesting that there are no common genetic factors between the conditions (Heun *et al.* 2001). This is important as the finding that LOD is associated with AD could be explained by LOD inducing AD, LOD being a prodrome for AD, or LOD and AD having common risk factors. Common environmental factors cannot be excluded but common genetic factors seem to have been. It seems unlikely that LOD might induce AD but disruption of the hypothalamic–pituitary axis has been suggested and some internal mediator of biological stress increasing the pathology of AD cannot be entirely discounted. However, it seems much more likely that LOD occurring in people in their sixth or seventh decades is in many cases an early manifestation of the AD process (Steffens *et al.* 1997; Schweitzer *et al.* 2002). However, depression as a symptom of dementia does seem to have some genetic factors, since siblings tend to share AD plus depression (Tunstall *et al.* 2000).

Differences between AD and normal ageing

Cognitive deficits of AD and normal ageing

There has been much controversy regarding the question as to whether AD is simply an extreme form of, or is qualitatively different from, normal ageing. The debate has raged on the grounds of cognition and brain changes. Part of the problem with regard to cognitive neuroscience is that the symptoms of normal ageing and AD are superficially similar in that memory begins to fail in both. However, the evidence is increasingly clear that if memory declines in late life, it is a secondary effect of processing ability in contrast to a primary failure of memory systems in AD. In late life, fluid intelligence, or problem-solving ability, is almost certainly affected (Denney 1985), although learnt skills and crystallised intelligence is not. Memory tasks involving processing of information are affected whereas the tasks that minimise working memory are relatively unaffected (Babcock & Salthouse 1990). Older people encode information poorly and are less effective in utilising strategies and instruction for retrieval (Verhaeghen & Marcoen 1996; Nyberg *et al.* 2002; West *et al.* 2002). All this amounts to some loss of effective memory together with a slowing of processing speed and changes in spatial cognition and language when they involve processing functions. In contrast, in AD there is primary loss of memory, language and spatial cognitive abilities. Milwain and Iversen (2002) argue that this difference between normal cognitive ageing and AD reflects the known anatomical location and spread of AD pathology. Thus AD commences in the limbic system, the seat of episodic memory, and it is this func-

tion that is lost first in AD but which is relatively unaffected in ageing. The pathology then spreads to the frontal and parietal association cortices in line with the primary semantic and spatial deficits of AD but not ageing. This raises the prospect of increasingly refined cognitive tests that might distinguish between normal ageing and the very early onset of AD (Nestor *et al.* 2004).

Brain changes of late-onset AD and normal ageing

All components of the cerebral pathology of AD may also be found in aged persons who have appeared to be mentally intact up to the time of death. Thus it has been argued that cerebral atrophy and its attendant histological changes are so common in later life that the structural state of the brain, as at present revealed, is of doubtful significance in relation to the disease process (Rothschild 1956). Some other qualitative differences might be waiting to be discovered, although this now seems unlikely, or alternatively it might be the mode of the patient's reaction to the ageing processes within the brain which holds the key to dementia.

It was the careful mapping of the neuropathology of the brains of elderly people combined with attention to their clinical features prior to death that really established late-onset AD as a disease entity, separate from normal ageing and akin to early-onset AD. The importance of the comprehensive studies of Corsellis (1962) and the series of reports from Newcastle upon Tyne (Roth *et al.* 1967; Blessed *et al.* 1968; Tomlinson *et al.* 1968, 1970; summarised by Roth 1971) cannot be overstated in this respect.

Corsellis (1962) examined the brains of a large group of aged patients who had died in a psychiatric hospital, and found a high level of agreement between the clinical diagnosis during life and the severity of the neuropathological changes. Both parenchymatous and vascular changes tended to become more common with advancing age, but the great majority of those diagnosed as suffering from dementia showed cerebral pathology of at least moderate severity compared with only one-quarter of those who had suffered from 'functional' mental disorders.

The Newcastle workers undertook prospective studies, beginning with clinical and psychometric observations during life, and compared these with quantitative measures of neuropathological changes after death. The subjects included elderly demented patients, patients with 'functional' psychiatric illness, and mentally well-preserved persons who had died from accidents or other acute illnesses. The non-demented elderly subjects frequently showed senile plaques (now often called neuritic plaques) in the cortex and neurofibrillary changes in the hippocampi. Outfall of cells and granulovacuolar degeneration were also seen in some degree in the absence of dementia. However, quantitative estimates of the number of plaques, or of the severity of neurofibrillary changes, proved to correlate very highly indeed with scores of intellectual and personality impairment. In

fact the relationship between impairment and mean plaque count was broadly linear. Moreover, plaques were present in all layers of the cortex in demented subjects, but often restricted to the superficial layers in those who had shown no intellectual decline. Very large conglomerate plaques were far commoner in demented than in normal subjects.

Wilcock and Esiri (1982) confirmed the Newcastle findings and focused particular attention on the significance of neurofibrillary change. Ball (1976) had already demonstrated an enormous increase in the number of tangle-bearing neurones in the hippocampi when AD patients were compared with age-matched controls, and Wilcock and Esiri sought to relate this to the severity of the dementia. Counts of both plaques and tangles were made in the cortex and hippocampi in patients with AD and in controls of equivalent age. Tangle formation proved to be highly correlated with the severity of dementia prior to death in the majority of areas sampled, in addition to distinguishing reliably between demented and non-demented subjects. Plaque counts showed significant associations of a similar nature but less impressively so. Moreover, tangle counts correlated with the severity of choline acetyltransferase reductions in the brain (Wilcock *et al.* 1982). It would appear therefore that the extensive development of neurofibrillary tangles may be of particular significance as a histological marker of AD. Tomlinson (1982) concludes from his considerable experience that while tangles can be found in the hippocampal pyramidal layer and occasionally in the hippocampal gyrus in healthy aged subjects, it is extremely rare to find them in the neocortex at any age in the absence of dementia. It might be added that the absence of neurofibrillary tangle pathology from the cerebellum, even in the context of heavy plaque load, is even more striking. Other more recent studies have confirmed that it is tangles rather than plaques that correlate best with severity of dementia (Nagy *et al.* 1995) but caution is warranted before over-interpreting these data: it may be, indeed some evidence suggests is likely to be, that tangles are relatively stable structures whereas plaques are more dynamic and can be removed by glia and possibly other processes. Furthermore, neither plaques nor tangles may be the 'cause' of dementia. Both may be the end-stage of the biochemical process that is actually the root cause of loss of neuronal function. Thus it may be oligomeric forms of amyloid invisible to the neuropathologist, or highly phosphorylated tau occurring years or decades before death, that results in dementia symptoms.

However, it does appear that AD arises clinically when the pathological changes of senescence develop beyond a certain degree of severity. In addition to these pathological lesions there is increasingly clear evidence of profound cell loss from the cortex when AD patients are compared with age-matched controls (Terry *et al.* 1981; Terry & Katzman 1983). Changes in the morphology of dendrites (Scheibel 1978) and reductions in their fields of arborisation (Buell & Coleman 1979, 1981)

have been reported. However, in contrast to this, in neurones containing tangles arborisation is actually increased (Gertz *et al.* 1991; McKee *et al.* 1989), perhaps as an attempt at compensation for loss of function.

A refinement of the distinction between AD and ageing comes with the argument as to whether AD is an age-related disorder or a disorder of ageing. The former suggests a disease state that is more common in a given age range (in this case age 75 to end of life) and the latter suggests a gradual and inevitable accumulation of brain damage with time. If the former, an age-related disorder, were the case, then it might be expected that incidence rates would fall at the upper end of the age range whereas they would continue to rise exponentially if AD were simply a function of age. The epidemiological evidence is not clear on this point for the obvious reason that it is very difficult to perform sufficiently large prospective studies of people at the very upper limits of the human lifespan. In an analysis of studies with approaching 30 000 pooled person life-years, the incidence in women continued to rise after the age of 90 whereas that in men started to fall (Andersen, K. *et al.* 1999). Even with studies of this size it cannot be concluded whether AD is an age-related disease or a disorder of ageing.

Investigations

Neuroimaging

Historically, neuroimaging has been used most in dementia to exclude other pathologies, some of which may be treatable. However, the cost-effectiveness of such a screening policy is highly dubious: in sequential series few if any potentially reversible conditions were identified by imaging that were not already suspected (Scheltens *et al.* 2002). Increasingly, however, the case is being made for neuroimaging to be used in the diagnostic work-up to enhance or refine diagnosis and not just to exclude other conditions (Knopman *et al.* 2001; Frisoni *et al.* 2003).

Cerebral atrophy, shown by widened sulci and enlarged ventricles on computed tomography (CT) or magnetic resonance imaging (MRI), is obvious in many patients, although overlap with age-matched controls prevents this from being used as a firm diagnostic criterion. Longitudinal studies have demonstrated that atrophy tends to worsen albeit with wide variability (Burns *et al.* 1991b; DeCarli *et al.* 1992). A more focused examination of the medial temporal lobe structures improves the diagnostic and prognostic value of structural imaging (Jobst *et al.* 1992; Horn *et al.* 1996; De Leon *et al.* 1997).

Hippocampal volume has most consistently been shown to be reduced early in AD and to be a marker of progression. Many studies have found evidence that medial temporal lobe structures, in particular hippocampal volume, are reduced early in AD and can be used to distinguish early AD from normal individuals (Convit *et al.* 2000; Jack *et al.* 2000;

Mizuno *et al.* 2000; Wahlund *et al.* 2000; Wolf *et al.* 2001). Some studies have shown a single MRI examination to provide a measure of atrophy that correlates with subsequent progression (Mungas *et al.* 2002). Scheltens *et al.* (2002) reviewed a series of studies that reported diagnostic sensitivity and specificity values ranging from 70% to 100% depending partly on the measures of hippocampal volume used and partly on the comparator groups in the studies. Overall, the sensitivity and specificity for detection of mild to moderate AD compared with controls was 85% and 88%.

Increasing attention is being paid to the possibility of using structural neuroimaging as a biomarker to measure change in AD. In particular, the studies of Fox and Rossor have shown that coregistration of serial MRI scans allows detection and quantitation of relatively subtle atrophic change (Fox *et al.* 2000). They find an annual change of 2.4% in AD compared with 0.4% in normal controls. Based on changes of this magnitude they are able to produce power calculations for the use of serial MRI as a biomarker of change in clinical trials of putative disease-modifying therapies, showing that for a year-long trial approximately 200 people in each arm of a trial would need to be assessed in order to have 90% power to detect a 20% effect-size of the drug (Fox *et al.* 2000). These figures compare very favourably with the numbers needed and the length of trial required were the sole outcome to be clinical change. De Santi *et al.* (2001) have suggested that although detecting change, coregistration of MRI is less sensitive than serial positron emission tomography (PET). Others have reviewed the evidence for the use of neuroimaging in measuring progression of AD (Kantarci & Jack 2003; Matthews *et al.* 2003).

Changes in cerebral blood flow and metabolism have been clearly demonstrated by functional imaging techniques. Early studies by Frackowiak *et al.* (1981), using PET, demonstrated substantial decreases in both cerebral blood flow and oxygen utilisation in SDAT, affecting both grey and white matter and implicating the parietal and temporal regions most severely. Sequential studies showed further decline with clinical deterioration, frontal hypometabolism appearing when deterioration was advanced. In contrast, the visual cortex and the primary sensorimotor cortex were relatively spared.

Mirroring blood flow, metabolism is also depressed in dementia (Pakrasi & O'Brien 2005). Using ^{18}F -fluorodeoxyglucose (FDG)-PET, Chase *et al.* (1984) observed relationships between hypometabolism in the left perisylvian region and language impairment, right posterior parietal region and visuospatial impairment, left angular gyrus and dyscalculia, and frontal hypometabolism in relation to personality change and attentional deficits. Haxby *et al.* (1988) found that frontal hypometabolism correlated with poor verbal fluency and attentional skills, whereas parietal hypometabolism was associated with impairment in verbal comprehension, arithmetical ability and visuospatial func-

tioning. Hypometabolism of brain in AD has been extensively confirmed using FDG-PET (De Leon *et al.* 2004; Mosconi 2005) and correlates with amyloid burden (Mega *et al.* 1999). In one systematic review the sensitivity and specificity of FDG-PET in the diagnosis of AD relative to controls was found to be 86% and 86%, respectively, (Patwardhan *et al.* 2004).

One interesting development has been the demonstration that these changes in metabolism are present in very young people at genetic risk of dementia (Bookheimer *et al.* 2000; Burggren *et al.* 2002; Reiman *et al.* 2004). It has been suggested that this marks the very early stages of dementia but an alternative possibility is that people carrying the *APOE* $\epsilon 4$ allele have instead a mild developmental difference in their brains and it is this that is related to increased risk of dementia in late life.

Proton magnetic resonance spectroscopy (^1H -MRS) has been used to examine the metabolic changes in the brain of a patient with AD, particularly *N*-acetylaspartate (NAA), a marker of neuronal integrity; creatine and phosphocreatine, markers of systemic energy use and storage; choline-containing compounds, markers of cell density and proliferation; and myoinositol, a possible marker of glial cells. The pattern of MRS changes in AD has been well established (Valenzuela & Sachdev 2001), showing reduced NAA and increased myoinositol. Concentrations of NAA correlate with plaque density and neurofibrillary tangles (Klunk *et al.* 1996) and reductions in NAA/creatine and phosphocreatine correlate with disease severity (Jessen *et al.* 2000).

Increasingly, functional MRI studies are being used to identify lesions in networks in AD and to search for evidence of plasticity and compensatory activity (Demetriades 2002; Devous 2002; Salmon 2002). However, possibly the most exciting prospect for the future is to develop molecular-based markers of AD processes. The first of these was a marker of amyloid formation used in PET studies (Cai *et al.* 2004; Klunk *et al.* 2004) but it is likely that other molecular markers will be developed and translated to more accessible imaging technologies including MRI.

Electroencephalography

Electroencephalography (EEG) shows abnormalities more frequently in AD than in any other form of dementia (Boutros & Struve 2002; Jeong 2004). The early stage consists of reduction of alpha activity, which may sometimes disappear entirely. This is particularly characteristic of AD and is perhaps of some value in distinguishing it from other varieties, in particular FTD where the EEG remains normal even relatively late in the disorder (Förstl *et al.* 1996). Later in the disease course in AD, diffuse slow waves appear, typically irregular theta activity with superimposed runs of delta. Focal or paroxysmal features are rare, even in patients with epileptic fits. Quantitative EEG may be useful in diagnosis in certain cases (Nuwer 1997).

Operational diagnostic criteria for AD

The diagnostic criteria for AD put forward by a working group established by the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA criteria) (McKhann *et al.* 1984) have become firmly established as a research, and to a large extent clinical, tool for diagnosing AD (Box 9.1). These criteria define probable and possible AD in life and definite AD as a post-mortem diagnosis (importantly accompanied by clinical features and not an exclusively neuropathological process).

In a prospective study of 50 elderly patients followed to post-mortem, Burns *et al.* (1990c) have shown the value of the NINCDS-ADRDA criteria. Of 32 patients diagnosed as 'probable' AD this was correct in 28, and of 18 'possible' cases the diagnosis was confirmed in 14 (i.e. sensitivities of 88%

and 78%, respectively). Mistakes mainly involved DLB in the former and vascular dementia in the latter. Jobst *et al.* (1998) found a specificity of 61% and a sensitivity of 96%. Lopez *et al.* (1999) found a similarly high sensitivity for AD but note that this condition is overdiagnosed. In a prospective study of over 2000 people coming to post-mortem, sensitivity was 93% and specificity 55% (Mayeux *et al.* 1998). These are remarkably consistent results and an American consensus group has expressed confidence in the use of both DSM and NINCDS-ADRDA criteria for clinical diagnosis of dementia (Knopman *et al.* 2001).

Course and outcome

The disease runs a progressive course, with death following some 2–8 years after onset. In Heston *et al.*'s (1981) material a trend could be seen for survival to increase a little from a mean of 7 years in those under 49 to 8.5 years for those aged

Box 9.1 NINCDS-ADRDA diagnostic criteria

I Diagnosis of probable AD

- Dementia established by clinical examination and documented by the MMSE, Blessed Dementia Scale or similar examination and confirmed by neuropsychological tests
- Deficits in two or more areas of cognition
- Progressive worsening of memory and other cognitive functions
- No disturbance of consciousness
- Onset between 40 and 90 years of age
- Absence of systemic disorders or other brain diseases to account for the progressive deficits in memory and cognition

II Such diagnosis is supported by:

- Progressive deterioration of specific cognitive functions such as language, motor skills and perception
- Impaired ADL and altered patterns of behaviour
- Family history of similar disorder, particularly if confirmed neuropathologically
- Laboratory results of normal lumbar puncture, normal EEG pattern or non-specific EEG changes, evidence of atrophy on CT with progression on serial observations

III Other features consistent with such diagnosis, after excluding other causes of dementia

- Plateaus in the course of progression
- Associated symptoms of depression, insomnia, incontinence, delusions, illusions, hallucinations, catastrophic outbursts, sexual disorders, weight loss and other neurological abnormalities (especially with more advanced disease) including increased muscle tone, myoclonus and gait disorder
- Seizures in advanced disease
- CT normal for age

IV Features that make such a diagnosis unlikely

- Sudden apoplectic onset
- Focal neurological signs such as hemiparesis, sensory loss, visual field deficits and incoordination early in the course
- Seizures or gait disturbances at the onset or very early in the course

V Diagnosis of possible AD

- May be made on the basis of the dementia syndrome, in the absence of other neurological, psychiatric or systemic disorders sufficient to cause dementia, and in the presence of variations in the onset, presentation or clinical course
- May be made in the presence of a second systemic or brain disorder sufficient to produce dementia, which is not considered to be the cause of the dementia
- Should be used in research studies when a single, gradually progressive severe cognitive deficit is identified in the absence of other identifiable cause

VI Diagnosis of definite AD

- The clinical criteria for probable AD and histopathological evidence obtained from biopsy or post-mortem

VII Classification of AD for research purposes

- Should specify features that may differentiate subtypes of the disorder, such as familial occurrence, onset before 65 years, presence of trisomy 21 and coexistence of other relevant conditions such as Parkinson's disease

55–74. In more elderly groups the survival was on average shorter, presumably due to deaths from competing causes, but even so the span could sometimes exceed 20 years. Seltzer and Sherwin (1983) made direct comparisons of 'relative survival time' between patients with onset before and after the age of 65 (by comparing observed length of survival for each individual with his expected survival from actuarial tables), and found significantly shorter survival for those in the presenile category. Rare cases are described in which the disorder becomes arrested for a time, but these must be regarded as exceptional. Neither remissions nor fluctuations characterise the disease.

A number of studies have attempted to use clinical features to try to define a subtype of aggressive AD or characteristics of more rapid decline. In a study of over 1000 patients, retrospective analysis found age at onset, MMSE, years of education, gender, ethnicity, living arrangement, presence of aphasia, delusions, hallucinations, and extrapyramidal signs to be independent variables associated with more rapid decline based on annual MMSE change (O'Hara *et al.* 2002). In line with this, in the Rotterdam study, age at onset and MMSE at presentation both predict decline (Ruitenberg *et al.* 2001a). The most consistent finding of many studies is that the worse the cognitive state at presentation, the worse the rate of subsequent decline and this holds true even in the very early stages of AD and prodromal AD (Lucca *et al.* 1993; Marra *et al.* 2000; Storandt *et al.* 2002). Aphasia and apraxia have been found by others to be predictors of rapid decline and mortality (Burns *et al.* 1991c; Yesavage *et al.* 1993). Loss of function is a predictor of mortality, and behavioural disturbance, perhaps unsurprisingly, a predictor of entry into nursing homes (Bianchetti *et al.* 1995). Once in a nursing home increased age, male sex, limitation in physical function, evidence of malnutrition, pressure sores, diabetes mellitus and cardiovascular disease predicts a more rapid decline to death (Gambassi *et al.* 1999).

Neuropathology

In a paper in 1907, Alzheimer described the clinical features and neuropathology of one of his patients, Auguste D. The lesions he described were subsequently shown by Corsellis and the Newcastle group to also occur in the brains of older people with dementia, thus suggesting that the two conditions were essentially the same, although there may be differences in aetiology and possibly in pathogenesis. The two key lesions are the amyloid or neuritic (previously senile) plaque and the neurofibrillary tangle.

Neuritic plaques (Fig. 9.1a)

These lesions are extracellular deposits of an amyloid, defined as an aggregated protein that has a high proportion of β -pleated sheet and shows birefringence when stained with Congo red. All amyloid deposits share this biochemical property but the parent molecules from which they are derived are different. In the case of AD the parent molecule is amyloid precursor protein (APP), the metabolism and genetics of which are discussed below. The neuritic plaque has a dense amyloid core surrounded by neuritic change and is visible on various silver staining techniques as pioneered by Nissl and utilised by Alzheimer, in addition to being readily visible with Congo red staining. When the amyloid peptide and its parent molecule were discovered, antibodies were developed that allowed the more subtle techniques of immunocytochemistry to be used on brain material. This revealed that the amyloid peptide was also deposited in diffuse aggregates that were not Congo-red positive. Strictly speaking these are therefore not amyloid deposits but this distinction is often lost. It is likely though that these diffuse plaques are precursors of the mature, neuritic plaque as seen by Alzheimer. The plaque is found in all cortical areas of brain and also occurs in striatum and the cerebellum (Braak *et al.* 1989; Braak and Braak 1990, 1991). There appears to be

Fig. 9.1 (a) Neuritic plaque and (b) neurofibrillary tangles (see also Plate 9.1).

relatively little correlation between overall plaque density and cognitive state (Nagy *et al.* 1995; Green *et al.* 2000), and plaque counts are not sensitive to differentiation between normal ageing and AD, although this may suggest simply that they are among the earliest changes of AD rather than indicating they are not pathological (Gold *et al.* 2001; Haroutunian *et al.* 1998). It is important to distinguish neuritic plaques from diffuse or non-neuritic plaques as the latter do correlate reasonably well with cognitive state (Dickson 1997). However, it is true that both plaques and tangles occur in people not known to have dementia (Davis *et al.* 1999; MRC CFAS 2001).

Neurofibrillary tangles (Fig. 9.1b)

Tangles are intraneuronal aggregates of a protein, tau, normally found in the axon. They are readily visible with silver staining techniques such as Bielschowsky: initially they appear as aggregates in the cell body, and then as they increasingly fill the cell body, particularly in pyramidal neurones, they appear as flame-shaped accumulations extending into the axonal hillock. Also seen with Bielschowsky staining are fine hair-like structures in the brain substance known as neuropil threads. Most probably these are tangles accumulating in the axons and dendrites of affected neurones. Under the electron microscope neurofibrillary tangles can be shown to be composed of many separate filaments, most appearing to be paired structures with a periodicity suggesting two twisted ropes. These are paired helical filaments and are abnormal and not to be confused with other normal filamentous structures in neurones such as neurofilaments and microtubules, of which more details will be given later. Paired helical filaments (and also straight filaments) occur not only in tangles but also in neuropil threads and in the neuritis surrounding neuritic plaques.

Tangles occur first in the entorhinal cortex and spread in a systematic fashion through hippocampus to wider cortical structures but always sparing the cerebellum (Braak *et al.* 1994; Braak & Braak 1998). In fact the important studies of Braak have shown that the earliest changes in neurones are an increase in tau phosphorylation and a redistribution of tau from the axon to the cell body. This appears to occur some years, possibly decades, before the clinical onset of dementia and both changes in tau phosphorylation and changes in tau expression and/or redistribution may be necessary precursors of the tau aggregation that results in tangle formation. It is not known, but is the subject of much interest and speculation, why some areas of brain are exquisitely sensitive and others apparently completely resistant to tangle formation. In advanced AD the distribution of tangles is very extensive and neurones in many areas become sparse. Tangles are insoluble and remain after the neurone dies, at which point the tangle is known as a 'ghost' or 'tombstone' tangle.

Other pathological changes in the AD brain

The steady accumulation of plaques and tangles is accompanied by synaptic loss (Adams 1991; DeKosky & Scheff 1990;

Terry *et al.* 1991) and this, together with actual neuronal loss, is likely responsible for most of the clinical features of AD. However, an effect of altered tau phosphorylation and redistribution, as observed by Braak as the earliest sign of AD pathology, on neuronal function cannot be excluded. Another lesion occurring in AD, the significance of which is unknown, is the granulovacuolar body, an intraneuronal change occurring often in pyramidal neurones. Amyloid material also occurs in amyloid angiopathy, in the walls of small vessels. As noted above, many studies have shown extensive non-amyloid atherosclerotic change in AD as well and it is becoming clear that this likely contributes to the disease process, possibly by accelerating plaque or tangle formation, possibly by affecting neuronal function or stability directly.

Neurochemistry

One of the most important breakthroughs in understanding AD was the realisation that it is, at least partially, predominantly a disorder of cholinergic neurones. The cholinergic hypothesis of AD rests on two main strands: evidence that cholinergic neurones are lost first and foremost in AD, and evidence from animal studies that cholinergic neurones are essential for memory. The evidence that cholinergic markers are lost most in AD came from the groups of Peter Whitehouse, Gordon Wilcock, Elaine and Robert Perry and others and demonstrated reductions in cholinergic neurones in the nucleus basalis of Meynert and reductions in markers of cholinergic activity there and elsewhere in the brain (reviewed in Francis *et al.* 1999). From animal work it was known that lesions of the cholinergic system, either surgical or chemical with the cholinergic antagonist scopolamine, induced cognitive defects in rodents. *In vivo* but indirect evidence in humans that lesions of the cholinergic system hasten decline in dementia comes from retrospective studies of those taking antidepressants or antipsychotics with anticholinergic actions (Holmes *et al.* 1997; McShane *et al.* 1997). The cholinergic hypothesis led to an intense effort to design compounds to increase cholinergic function including precursor therapies such as lecithin, receptor agonist approaches and the cholinesterase inhibitors. It was this latter approach that proved the first successful drug therapy in AD.

Despite this outstanding success, the cholinergic hypothesis is only part of the story as far as neurochemical attrition in AD goes. Lyness *et al.* (2003) reviewed all the studies on regional cell loss in AD published between 1966 and 2000 and performed a meta-analysis of relative cell loss. Compared with the dopaminergic substantia nigra, where there is relatively little cell loss, the attrition was greatest in the cholinergic nucleus basalis and the noradrenergic locus coeruleus, closely followed by the serotonergic dorsal raphe nucleus. This huge analysis of a considerable body of work stretching two decades demonstrates that there is extensive loss of noradrenergic and serotonergic neurones, with loss of the former being as extensive as loss of cholinergic tracts and

suggests that there may be some merit in replacing these functions in addition to replacing cholinergic function.

There is less convincing evidence for glutamatergic deficits in AD (Cowburn *et al.* 1990), although there is some evidence of decreased glutamate *in vivo* from MRS studies (Antuono *et al.* 2001; Hattori *et al.* 2002).

Molecular biology

Formation of amyloid

Research in AD entered a new phase when David Allsop, then separately Glenner and Wong, and Beyreuther and Masters, discovered the nature of the amyloid protein core of the plaque first observed by Alzheimer (Allsop *et al.* 1983; Glenner & Wong 1984; Masters *et al.* 1985). Glenner and Wong noted that 'This protein may be derived from a unique serum precursor which may provide a diagnostic test for Alzheimer's disease and a means to understand its pathogenesis'. These predictions have largely been borne out. The peptide is indeed derived from a larger precursor, fragments of which can be detected in serum although the whole protein itself is cell-bound. Using these fragments as biomarkers has not proved possible but certainly the pathogenesis of the plaque has become understood and 20 years after this seminal study compounds designed to reduce amyloid formation are entering clinical trials.

The precursor from which the amyloid peptide (known as A β) is derived is APP, a nearly ubiquitous protein present in all cell types and showing a large degree of cross-species homology (Kang *et al.* 1987). The role of this protein is not fully understood but it is becoming increasingly clear that it is a complex molecule that serves not a single but many functions. One role is to act as a cellular receptor (specifically as a G protein-coupled receptor, where binding to APP would be expected to induce signalling events, the nature of which are as yet unknown) (Nishimoto *et al.* 1993). Another suggestion is that as a molecule with a large extracellular region, APP

might function in cell-cell contact or adhesion events, possibly at the synapse. The metabolic products of APP have functions quite distinct from those of the intact molecule. The APP fragment released by cleavage at the cell membrane (sAPP α) functions as a complement factor inhibitor and the intracellular fragment released by cleavage of APP within the cell membrane translocates to the cell nucleus and is involved in gene transcription events (Cao & Sudhof 2001). These are just two of many actions and sAPP α , A β and the other metabolic products of APP have many binding partners, all of which suggest a complex biology. It is widely assumed that the critical events in AD are not so much loss of this rich biology but a toxic gain of function, a neurotoxicity due to the A β fragment. However, it is worth bearing in mind that APP and its fragments have important roles to play in memory and cognition (Turner *et al.* 2003). This is most apparent in relation to long-term potentiation, the process whereby neurones, most often in hippocampus, can be shown to 'remember' a rapid and strong electrical stimulus. The excitatory postsynaptic potential increases in response to such a tetanic stimulus and this increased response is then replicated even for milder subsequent stimuli: the neurones have been potentiated (Bear & Malenka 1994). This protein synthesis-dependent process is the best available cellular correlate of memory and is consistently inhibited by A β (Turner *et al.* 2003).

Amyloid precursor protein is metabolised by three secretase activities: α -secretase, β -secretase or β -amyloid cleaving enzyme (BACE), and γ -secretase (this has been extensively reviewed; see for example Haass & De Strooper 1999; Wilson *et al.* 1999; Allinson *et al.* 2003) (Fig. 9.2). The site for α -secretase is within the moiety itself and so cleavage by this route cannot yield intact A β and hence this pathway is known as non-amyloidogenic. On the other hand, sequential cleavage by BACE and then γ -secretase yields fragments of 40–42 amino acids in length. A β -42 is more likely to form fibrils *in vitro* (as occurs in the plaque in the AD brain) and is therefore

Fig. 9.2 Metabolism of amyloid precursor protein.

Fig. 9.3 Tau phosphorylation and aggregation.

thought to be more pathogenic than A β -40. The identity of these various enzymes has been sought with vigour as these are obvious sites for therapeutic intervention. BACE and its homologue BACE2 has been identified and cloned (Saunders *et al.* 1999) and inhibitors have been produced that might have potential as therapies to prevent amyloid formation (Potter & Dressler 2000). For various reasons, not least the fact that loss of the gene is fatal to mice, targeting γ -secretase for therapy is harder. However, the identity of this interesting enzyme has been shown to reside within a complex of proteins that includes presenilin-1 (see below), nicastrin, APH-1 and PEN-2 (De Strooper 2003). This γ -secretase complex is of fundamental importance to the brain as in addition to cleaving APP it also cleaves a protein Notch responsible for lateral inhibition, the process whereby one precursor cell adopts a neuronal cell fate and signals to its neighbours to choose other destinations (Beatus & Lendahl 1998). One Notch gene is involved in the disorder CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy), an inherited condition with migraine, stroke, neuropsychiatric symptoms and dementia (Davous 1998). It would not be surprising to find Notch and its related genes involved in other neuropsychiatric conditions.

Formation of tangles

Neurofibrillary tangles are composed of the microtubule-associated protein tau, present in tangles in a highly phosphorylated form and aggregated into paired helical filaments. Normally, tau binds to and stabilises microtubules, which are essential for axonal transport (reviewed in Goedert 1993; Paglini *et al.* 2000). Much of psychiatry and neurology concentrates on synaptic events but this is mere

expediency secondary to the availability of drugs that happen to work at the synapse. However, the synapse has little or no protein-generating capability and all the functional proteins, or their subunits or precursors, at the synapse have been generated in the cell body and then transported down axons. This fast axonal transport is microtubule dependent and in turn tau dependent, as tau and other microtubule-binding proteins are responsible for maintaining the integrity and function of the microtubules. In AD, tau is highly phosphorylated and the microtubule-binding properties of tau are regulated by phosphorylation (Fig. 9.3). The highly phosphorylated tau of the AD brain fails to effectively bind to microtubules and in cells fails to stabilise them. It is noteworthy that in the AD brain, neurones affected by tangle formation lack a normal microtubule cytoskeleton. This suggests that the regulation of tau phosphorylation is critical in AD (Lovestone & Reynolds 1997). A considerable body of work now suggests glycogen synthase kinase (GSK)-3 as a predominant but probably not exclusive tau kinase. GSK-3 is an interesting enzyme as it is effectively inhibited by lithium, although whether this is responsible for lithium's therapeutic or toxic actions is unclear (Eldar-Finkelman 2002).

Amyloid cascade hypothesis

The finding of mutations in the *APP* gene associated with familial early-onset AD (FAD; see Genetic factors, later) demonstrated that APP was fundamental in the pathogenesis. Mutations in the gene tend to occur at or close to the sites of amyloidogenic cleavage by BACE and γ -secretase and this very strongly suggests that dysregulation of APP metabolism is an early event in AD pathology. This is the basis of the amyloid cascade hypothesis (Fig. 9.4), in which altered regu-

Fig. 9.4 Amyloid cascade hypothesis.

Fig. 9.5 Sites of possible amyloid-based therapeutics.

lation of APP would yield increased Aβ and this in turn would induce tau phosphorylation, aggregation into tangles, neuronal death and hence dementia (Hardy & Higgins 1992). One and a half decades later, this hypothesis has not been seriously challenged, although it has been extensively refined in its detail (Mudher & Lovestone 2002). Remarkably, all the fundamental predictions of the model have been confirmed; most importantly the observation that all the known mutations causing FAD increase either total Aβ or the more fibrillogenic Aβ-42. The gap in the hypothesis is most obvious between amyloid and tau: in neurones in culture Aβ-42 is toxic and induces tau phosphorylation, most likely by inducing GSK-3 activity (Takashima *et al.* 1998; Alvarez *et al.* 1999). However, in transgenic mice massive deposition of amyloid in animals carrying the FAD mutations does not result in

extensive tau phosphorylation, no tangles and little or no evidence of a dementia. This fact suggests a critique of animal modelling of human disease rather than a serious objection to the amyloid cascade hypothesis.

Disease-modifying therapy and the amyloid cascade hypothesis

The huge accumulation of evidence in favour of the cascade starting with amyloid and ending with tau suggests therapies for AD many of which are in development (Fig. 9.5). Drugs to reduce Aβ formation such as BACE inhibitors have been developed, as have small-molecule inhibitors of Aβ aggregation. An alternative approach would be to increase clearance of amyloid deposits from the brain and one of the most promising developments was the demonstration that

passive or active immunisation did just this in mouse models. Unfortunately, the same in humans proved toxic, although there was evidence that plaque load was reduced (Nicoll *et al.* 2003). The immunisation approach is being modified in an attempt to reduce the toxicity while retaining amyloid-clearance efficacy. Breaking the link between amyloid and tau is being pursued, not least with GSK-3 inhibitors. Determining whether any of these approaches actually reduces the pathology in brain given that there are few biomarkers and no actual markers of pathology is a challenge.

Genetic factors

Early-onset autosomal dominant FAD

The only subclassification of AD that has biological justification is between familial forms and non-familial forms. However, even this is complicated by the fact that there is a considerable genetic component even to the apparently non-familial forms. Individual families with pedigrees suggestive of autosomal dominant inheritance had long been recognised and when linkage in some of these families was mapped to a region on chromosome 21, attention turned to the obvious candidate in this region, APP. After some initial confusion caused by genetic heterogeneity between families, a mutation in the APP gene resulting in a valine/isoleucine change at position 717 of the APP protein was found in a family from London by the group led by John Hardy, then working at St Mary's Hospital. Subsequently, other mutations were found in the same region of the gene. This region is at the γ -secretase site and it is likely that coding changes in the amino acid sequence alter the activity of γ -secretase on the APP protein. In cells and in transgenic animals, overexpression of human APP with these mutations results in increased A β -41 formation and plaques. Subsequently, a double mutation in the region of the gene coding for the sequence recognised by BACE was found in a Swedish family (*APP^{swe}*) and, as for other mutations in APP, this change (at position 670/671) results in A β formation and plaque formation in animal models. All this is powerful evidence in favour of the amyloid cascade hypothesis, but even more compelling evidence for the hypothesis comes from the fact that mutations within the A β moiety of APP do not result in increased A β formation in model systems and do not cause classical AD but instead hereditary cerebral haemorrhage with amyloidosis (Dutch type) or variants of this condition. In 2005, there were 16 known pathogenic mutations in the APP gene, with new mutations being posted at <http://www.alzforum.org/res/com/mut/default.asp> as they are reported. However, there are some families with apparent linkage to chromosome 21 that do not have APP mutations and it may be that there are other disease loci on this chromosome. It is likely that the reason why AD neuropathology is an invariable accompaniment of Down's syndrome (Mann 1988) is trisomy APP.

It was known that other families with FAD showed linkage to chromosomes 14 and 1 and mutations were eventually found in a novel gene named presenilin 1 (PS-1 for protein, *PSEN1* for gene) on chromosome 14. A swift hunt through the human genome database found a homologous gene on chromosome 1 and, as predicted, mutations in this gene in an ethnic group showing chromosome 1 linkage (Volga German people). To date there are over 70 mutations in *PSEN1* known to cause AD, with new mutations still being reported. It is still not known whether these mutations result in a toxic gain in function or a loss of normal function but it is clear that the end-result is a change in APP processing. Transgenic animals have been generated harbouring both *PSEN1* and *APP* mutations with consequent increased amyloid pathology (but surprisingly little tau pathology).

The age of onset in families carrying *PSEN1* mutations tends to be earlier, and those carrying *PSEN2* mutations later, than those with *APP* mutations. However, there is considerable variation between families and even to a degree within families. Non-penetrance of a *PSEN1* mutation has been reported but not (yet) for *PSEN2* or *APP* (Rossor *et al.* 1996). Based on linkage, to chromosome 3 for example, there are likely to be one or two other genes causing FAD. Mutations in the *TAU* gene have been found in FTD and there are reports of familial motor neurone disease with dementia, the genes for which have not yet been reported (although linkage results suggests a gene on chromosome 9). It will be important to determine the biological relationship between these genes, and disorders with few clinical similarities may turn out to have considerable mechanistic and pathological overlap.

The genetics of FAD has been extensively reviewed (Clark & Goate 1993; Hardy 1996; Price *et al.* 1998; Selkoe 2000). It has undoubtedly been the most important spur to understanding the molecular pathogenesis. However, it is important to recall that FAD is an extremely rare condition, occurring in perhaps 5 per 100 000 population at risk (Campion *et al.* 1999), a figure that equates to approximately 600 people in the entire UK (Liddell *et al.* 2001). Nonetheless, for these families precise diagnosis of AD can be made in life and predictive testing can be offered (Liddell *et al.* 2001). This should only be performed in the context of a clinical genetics department and there is international agreement that protocols developed for Huntington's disease should be followed (Lovestone 1999). These include first determining a mutation in an affected family member (and for AD determining that a mutation is indeed pathogenic – not a trivial task). Counselling should be offered and would normally take place over 3–6 months; people at 25% a priori risk (i.e. grandchildren) should not be tested as this would provide a de facto prediction on the intermediary generation, and caution should be exercised in those with serious affective or other psychiatric features (Lovestone & Lashwood 2001).

Late-onset AD

Previously, late-onset AD was thought to be largely a sporadic condition, although a family history is found in up to one-third of patients. However, the most important reason for lack of family history is attrition due to other diseases: relatively few of the currently aged cohort have sufficiently large and aged pedigrees to be informative. Clearly if both parents die before the age of onset of AD (say before 75–80), then one cannot infer anything from a lack of family history. A series of studies instead examined age-related incidence of AD in family members, finding a cumulative incidence by the age of 90 years of up to 50% (Breitner *et al.* 1988; Huff *et al.* 1988; Farrer *et al.* 1989; Korten *et al.* 1993). This demonstrates the importance of susceptibility genes that do not cause but increase risk of AD. From twin studies, it has been estimated that the heritability of late-onset AD is 60–70% (Bergem *et al.* 1997; Gatz *et al.* 1997; Pedersen *et al.* 2001), of which one gene (*APOE*) accounts for less than half of the genetic variance (Owen *et al.* 1994) and with an estimated four or more genes waiting to be discovered (Daw *et al.* 2000). In very late-onset AD the importance of genetic factors appears to diminish (Silverman *et al.* 2003).

One unequivocal genetic susceptibility locus for AD has been discovered, the *APOE* gene. There are three common variants or alleles of the gene, *APOE*ε2, *APOE*ε3 and *APOE*ε4, differing by only two single-nucleotide polymorphisms (SNPs) that result in two different amino acid changes. The *APOE*ε4 variant increases risk, by perhaps threefold to fourfold in the heterozygote state and up to 10-fold in the homozygote state. At the age of 65 this has the effect of a threefold difference in life expectancy between *APOE*ε4 carriers and non-carriers (Seshadri *et al.* 1995), but at earlier ages the effect on life expectancy is negligible (even though *APOE*ε4 also increases risk of cardiovascular disease in men). *APOE* only modulates risk and does not 'cause' the disease; as *APOE*ε4 is not the commonest variant, the majority of people with AD do not carry this risk gene. In fact, it may be that *APOE* only alters risk at all by altering the age of onset of AD, with *APOE*ε4 carriers acquiring the disease earliest and *APOE*ε2 carriers the latest (Meyer *et al.* 1998). This has been characterised as *APOE* affecting 'when and not if' AD occurs.

The means by which *APOE* alters risk are not known. The *APOE*ε2/3/4 variant is a major mediator of cholesterol levels and so the risk may not be directly on the brain at all. Alternatively, *APOE* has been shown in different studies to affect Aβ aggregation and clearance, tau phosphorylation, synaptic plasticity and numerous other processes that could plausibly be important in AD. Given the robust association between *APOE*ε4 and AD, considerable thought has been given to whether genetic testing for this gene could contribute to diagnosis or prognosis or whether there are pharmacogenetic uses for testing. This has been the subject of a number of consensus groups (see for example Brodaty *et al.* 1995; Farrer *et al.* 1995; Alzheimers Association and National Institute for

Aging 1998), which have concluded that there are no clinical roles for testing as *APOE* genotype does not improve diagnostic accuracy enough to warrant its use, confers too little risk to be of value in prediction and does not have any replicated effects on response to cholinesterase inhibitors. However, it is likely that at some point there may be some use for genetic testing in late-onset AD, perhaps with a combination of genes or to predict conversion from mild cognitive impairment. This is a prospect anticipated with some trepidation by many. It is sobering that the decade from 1993 to 2003 of accumulated research on the genetics of late-onset AD yielded one gene of uncertain function and no clinical utility and has led to no significant insights into the pathophysiology of AD. Although almost certainly an essential and inevitable research strategy, it demonstrates that the genetics of complex common conditions is no rapid route to therapy.

A huge number (more than 100 in 2003) of other genes have been reported to be associated with late-onset AD in case-control association studies. However, none of these have yet been reliably replicated, emphasising the difficulty currently facing attempts to find genetic susceptibility factors for many common and complex diseases. It is something of a puzzle and a huge concern as to why it has proved so difficult to replicate findings. It might be that all these 100 or so putative associations are false positives or it might be that due to study population stratification, associations that are true for a subgroup (by gender, age, ethnicity or any one of a myriad of other factors) appear in one study but not another. It is likely that this difficult and frustrating situation will only be resolved by studying very much larger groups (thousands rather than the hundreds typical of most studies). An alternative approach is to perform linkage on related individuals and a series of such studies concur that there is a region on chromosome 10 associated with AD, although the actual genomic regions in these various studies do not completely overlap (Bertram *et al.* 2000; Ertekin-Taner *et al.* 2000; Myers *et al.* 2000; Li *et al.* 2002; Blacker *et al.* 2003).

Genotype–phenotype correlations

There is a considerable amount of evidence that individual variation in the phenotype of AD (the manifestation of the illness in a particular individual) may have a genetic component. In siblings with AD, depression and agitation are shared traits and depression may be more frequent in first-degree relatives of probands with AD and depression (Pearlson *et al.* 1990; Tunstall *et al.* 2000). Some of the genetic component responsible for this variation in the pattern of non-cognitive symptoms has been shown, in replicated studies, to lie in 5-hydroxytryptamine and dopaminergic receptor polymorphisms (Holmes *et al.* 1998, 2001; Sweet *et al.* 1998; Nacmias *et al.* 2001). Age of onset of AD is also inheritable, most obviously in the autosomal dominant families where age of onset has some constancy within

families (Mullan & Crawford 1994) but also due to *APOE* variation (Meyer *et al.* 1998) and a locus on chromosome 10 (Li *et al.* 2002). The relationship between genetic factors and BPSD has also been examined through linkage studies, with some evidence for genetic loci on chromosomes 2, 6 and 21 influencing the occurrence of psychosis in AD (Bacanu *et al.* 2002).

Environmental risk factors

Of all the risk factors for AD, age is overwhelmingly the most important, doubling the risk every year after the age of 65. So important is this that it has led some to speculate that AD is an invariable accompaniment of ageing (Ritchie & Kildea 1995). In line with this are studies showing accumulation of AD pathology in the elderly without apparent dementia (MRC CFAS 2001) and epidemiological studies showing no decrease in incidence in very elderly women (Andersen, K. *et al.* 1999), although the finding that incidence falls in very elderly men would counter this somewhat. However, even this most apparently obvious environmental risk factor may have an inherited component as there is an interesting interaction between age and genetic factors, with the only confirmed risk factor for AD altering age of onset rather than having absolute risk of suffering the condition (Breitner *et al.* 1999; Meyer *et al.* 1998). Family-based studies confirm that age of onset tends to be shared by siblings and that not all of this sharing is accounted for by *APOE*, suggesting that other genetic loci are involved (Tunstall *et al.* 2000) and a linkage study shows a region on chromosome 10 associated with earlier age of onset not only of AD but also Parkinson's disease (Li *et al.* 2002). These findings serve to emphasise that the distinction between gene and environment is an entirely false one and that it is interaction between the gene and environment that is critical.

Head injury: effects on amyloid and tau related pathology

A reasonably large number of case-control studies have suggested that closed head injury resulting in some loss of consciousness is commoner in people with AD. A meta-analysis of these studies confirmed an increased risk of head injury with a relative risk of 1.8 (Mortimer *et al.* 1991). However, in a later meta-analysis, subsequent studies showed no increase in risk. Overall, including all 15 studies examining the association, a modest increase of risk with an odds ratio (OR) of 1.6 was found, although this was entirely due to an increased risk in males exposed to head injury (Fleminger *et al.* 2003). Although the risk due to head injury is only modest and not entirely replicable, there is a clear mechanism to explain such an association as studies of brains of people dying of head injury show increased amounts of amyloid peptide deposition (Roberts *et al.* 1994). It is likely that this is a neuroprotective response, but one that can in some people who survive

the head injury go on to induce the changes of AD. In addition, repetitive head injury not resulting in loss of consciousness is associated with dementia, for example the dementia pugilistica syndrome of boxers. The shearing action on axons that accompanies such blows to the head induces extensive damage, including tau aggregations similar to those of AD and also deposition of amyloid peptide (Roberts *et al.* 1990). Some studies have been able to demonstrate that this deposition of amyloid is increased in people carrying at least one *APOEε4* allele and that clinical response to brain injury is *APOE* dependent (Horsburgh *et al.* 2000), suggesting another gene-environment interaction although evidence for such an interaction in clinical studies of head injury and AD is lacking (Mortimer *et al.* 1991).

Vascular factors

Vascular dementia is partly defined by the presence of vascular risk factors but it is probably true that these same factors also increase risk of AD itself. Thus hypertension, smoking and peripheral artery disease are all associated with AD (reviewed in Prince 1995; Fujishima & Tsuchihashi 1999; Skoog *et al.* 1999). The clearest association between AD and vascular risk factors (as distinct from those studies examining all dementias and vascular risk where the association may obviously be confounded by vascular dementia) is between hypertension and AD. However, even here, some cautionary notes are warranted. Thus, for example, Qiu *et al.* (2003) find an association between hypertension and AD with an OR of 1.5 but also find an association with low blood pressure. In contrast, Posner *et al.* (2002) show that hypertension is not associated with increased risk of AD demonstrating, if nothing else, that epidemiological associations can be as hard to replicate as genetic ones. However, the importance of this risk factor is the straightforward means of preventing it, and one study has demonstrated that treating hypertension can reduce the risk of AD (Forette *et al.* 2002). There is a possible gene-environment interaction between hypertension and AD in that the gene encoding angiotensin-converting enzyme (ACE) is associated with both, although it has to be said that the association is not consistently replicated in either condition (Kehoe *et al.* 1999; Schunkert 1997). In addition, an interaction between *APOE* and vascular risk is reported in some studies (Hofman *et al.* 1997; Stewart *et al.* 2001) but not all (Prince *et al.* 2000). Neuropathological studies have consistently shown a high degree of overlap between vascular and AD pathologies (Holmes *et al.* 1999; MRC CFAS 2001) but it is also true that minor amounts of vascular damage are common in the population, for example 34% in controls compared with 43% in neuropathologically confirmed AD cases in one study (Jellinger & Attems 2003).

A raised homocysteine level is a highly reproducible risk factor for vascular disease and has been consistently shown to be associated with AD (Clarke *et al.* 1998; McIlroy *et al.* 2002; Shea *et al.* 2002; Miller *et al.* 2003; Nagga *et al.* 2003;

Religa *et al.* 2003; Selley 2003). Whether this association is mediated through vascular damage inducing AD, through an association with vascular dementia *per se* or some other neuronal effect altering the AD pathogenic process is not known. However, it does raise the possibility of preventive measures to reduce homocysteine levels using dietary folate supplementation. Early trials have not shown any benefits on cognition in healthy elderly or in people with dementia, although long-term preventive trials have not yet been performed (Malouf *et al.* 2003; Sommer *et al.* 2003).

Inflammation and non-steroidal anti-inflammatory drugs

Following the important observation that AD appeared rare in conditions such as leprosy and arthritis, a series of studies examined the effects of non-steroidal anti-inflammatory drugs (NSAIDs) on the incidence of AD. Reviewing the literature, McGeer *et al.* (1996) noted the apparent protection offered by both steroids (OR 0.7) and NSAIDs (OR 0.5). Subsequent studies have all confirmed this finding but it seems to be that long-term use of these drugs is necessary to confer protection (Stewart *et al.* 1997; in't Veld *et al.* 2001; Zandi *et al.* 2002a). The clear finding from epidemiology that NSAIDs and other anti-inflammatory drugs are protective chimes with findings from neuropathology that there is extensive inflammatory change in the AD brain (reviewed in Akiyama *et al.* 2000). There is an excess of microglia, many associated with neuritic plaques, and extensive evidence of upregulation and secretion of inflammatory response proteins such as complement and its constituents, the cytokines and acute-phase proteins. A gene-environment interaction has been sought and a number of genetic factors relevant to inflammation have been associated with AD but none reliably replicated.

It is tempting to speculate that the inflammatory process in AD is initiated by plaque formation and, as in other inflammatory diseases, progresses to the point where it causes local damage thus creating a spiral of disease. However, more recent evidence suggests that some but not all NSAIDs alter the processing of APP, possibly by activating either, or both, BACE and γ -secretase (Weggen *et al.* 2001, 2003; Sastre *et al.* 2003). It is interesting that not all NSAIDs are equal in this respect, and noteworthy that ibuprofen, one of the drugs that alters APP metabolism, reduced pathology in the brains of mice overexpressing APP, with evidence of a reduction in the formation of the soluble amyloid peptides that form plaques (Lim *et al.* 2001). If the action of NSAIDs on APP were the mechanism of effect in offering protection against AD then only some compounds would be expected to be protective, whereas if the mechanism were directly on inflammation then all anti-inflammatories should be efficacious. A series of trials have reported no protection with a variety of NSAIDs and cyclooxygenase (COX)-2 inhibitors (NSAIDs are joint COX-1 and COX-2 inhibitors) without any success. However,

it is too early to conclude whether this is because non-APP-altering drugs have been used or whether the failure to demonstrate an effect is due to trial design – too late in the disease process, too short or too small.

Diabetes: insulin signalling defect or vascular insult?

A series of epidemiological studies have demonstrated that diabetes increases risk of dementia (reviewed in Stewart & Liolitsa 1999; Gasparini *et al.* 2002), with only one study showing no association (MacKnight *et al.* 2002). An obvious explanation for this association would be that diabetes causes vascular disease and that it is this that in turn causes the dementia. If this were the case, then diabetes should be associated with vascular dementia and not AD. Both case-control and cohort studies have attempted to determine whether this association is due to vascular dementia or AD or both, with mixed results: some suggest that both are increased in those with diabetes (Peila *et al.* 2002), some that diabetes increases the risk of vascular dementias (Katzman *et al.* 1989; Boston *et al.* 1999; Hébert *et al.* 2000) but not AD (Nielson *et al.* 1996; Curb *et al.* 1999; Hassing *et al.* 2002), one that diabetes increases risk of AD but not vascular dementia (Brayne *et al.* 1998), and three large longitudinal cohort studies show that diabetes is a risk factor for AD independently of whether or not it is a risk factor for vascular dementia (OR 1.3–1.9) (Ott *et al.* 1996, 1999; Luchsinger *et al.* 2001).

Other evidence points to a specific defect in insulin signalling (i.e. insulin resistance) in AD (Winograd *et al.* 1991; Meneilly & Hill 1993) and insulin resistance itself appears to be a risk factor for AD (Kuusisto *et al.* 1997). Thus it has been shown that there is increased plasma and CSF insulin both at baseline (Craft *et al.* 1998) and after oral glucose load in AD compared with controls (Fujisawa *et al.* 1991) and that impaired serum insulin response to hyperglycaemia correlates with cognitive impairment even after controlling for vascular factors (Stolk *et al.* 1997) and also with dementia progression (Craft *et al.* 1993). This is in line with post-mortem evidence that brain insulin receptors are increased in AD (Hoyer *et al.* 1998), suggesting upregulation in response to resistance, and tyrosine phosphorylation, an insulin signalling event, is reduced in AD (Frolich *et al.* 1999). Insulin has been shown to regulate both the metabolism of APP (Solano *et al.* 2000) and the phosphorylation of tau (Hong & Lee 1997), in both instances reducing the processing of these proteins that leads to pathological lesions in AD. Mice with disrupted insulin signalling, induced by either diet or targeted genetic lesions, have increased tau phosphorylation (Yanagisawa *et al.* 1999; Planes *et al.* 2001; Schubert *et al.* 2003).

Given that insulin resistance and diabetes increase the risk of AD, it follows that susceptibility loci associated with insulin resistance/diabetes might also be risk factors for AD. Three studies provide tentative evidence that this may be the case. In Pima Indian women, polymorphic variation in a phosphatidylinositol 3-kinase subunit, P85 α , is associated

with insulin resistance and diabetes and the same SNP increased AD risk in women but not men, analogous to the pattern of risk in relation to diabetes, with an OR of 2 (Liolitsa *et al.* 2002). Others have shown variation in the insulin receptor gene to be associated with earlier onset of AD (Majores *et al.* 2002), and variation in PPAR α (peroxisome proliferator-activated receptor), also involved with glucose metabolism, to be associated with dementia (Brune *et al.* 2003). The usual caveat, that none of these studies have yet had replications published, remains.

Education: 'use it or lose it' and the brain reserve hypothesis

Case-control studies have tended to suggest that remaining in education for longer offers some protection against dementia (Schmand *et al.* 1997). In some studies this was due to an effect of education on non-Alzheimer dementia (Fratiglioni *et al.* 1991; Cobb *et al.* 1995) and education may be a confounder in that it independently affects scores on dementia screening instruments (O'Carroll & Ebmeier 1995), possibly resulting in lower rates of detection in the highly educated. However, a series of large epidemiological studies do suggest a direct interaction between education and AD (Evans *et al.* 1997; Launer *et al.* 1999; Letenneur *et al.* 1999; Qiu *et al.* 2001). Most convincing has been the Nun study where a protective effect of education was suggested by the association of complex language use in young adults with decreased AD pathology many decades later (Butler *et al.* 1996; Mortimer *et al.* 2003).

Explaining the apparent association between education and protection against AD has proved difficult. That longitudinal studies confirm the case-control studies does tend to negate the parsimonious explanation that people with high levels of education are simply not detected as having dementia. There is an interaction between gender and education in that it is only in women that an effect is seen (Letenneur *et al.* 2000), but this does not provide an explanation of why there is an effect. Interestingly, in a study of African-Americans there was an interaction between education and place of residence, suggesting that living in an urban environment increases risk of AD and that low education might just be a marker of a protective, rural lifestyle (Hall *et al.* 2000). Others have found early-life factors to alter the risk of AD but that education does not modify this effect (Moceri *et al.* 2000). Alternatively, it may be that education is a marker of mid-life protective factors and there is reasonably consistent evidence that increased physical and mental activity offers some protection against AD (Friedland *et al.* 2001; Laurin *et al.* 2001; Lindsay *et al.* 2002; Wilson *et al.* 2002). Maybe the highly educated stay active longer. This might be considered the 'use it or lose it' hypothesis. An alternative possible explanation of the protection offered by education is the 'cognitive reserve' hypothesis, which broadly stated postulates that those with more education have more function and can therefore sustain

a greater neurodegenerative 'hit' than those with fewer reserves. Quite what cognitive reserve equates to in the brain is pure conjecture, presumably networks, neurones or synapses. In this context it is both intriguing and perhaps surprising that head circumference is also associated with risk of dementia, a larger head offering some measure of protection (Schofield *et al.* 1997; Borenstein *et al.* 2001), although small neuroimaging studies are less supportive of this finding (Jenkins *et al.* 2000; Edland *et al.* 2002). The combination of small head and low education is particularly risky as far as AD is concerned (Mortimer *et al.* 2003). Perhaps big heads mean big brains, which in turn means more brain to lose before dementia becomes apparent. Most interestingly in this context, animals that overexpress the tau-kinase GSK-3 have very small brains (Spittaels *et al.* 2002).

Gender and the role of estrogen

Women are over-represented in all cohorts of the elderly and especially so in those with dementia and AD in particular. However, this is not just due to the increased longevity of women as the incidence of AD is greater in women than in men and the risk of vascular dementia is not increased (Andersen, K. *et al.* 1999). Nevertheless, the increase in incidence was only apparent in the very elderly in at least one large prospective study (Ruitenberg *et al.* 2001b). Assuming that there is a true increase in incidence for women, what might this be due to? The most obvious mechanism is the loss of protection of estrogen and related hormones after the menopause and there is ample evidence that estrogen has some neuroprotective properties, particularly against amyloid-induced neurotoxicity (Green *et al.* 1996; Mook-Jung *et al.* 1997; Svensson & Nordberg 1999). Then it was found that hormone-replacement therapy (HRT) offers protection against AD and might even mitigate against some of the cognitive loss once the disease has started (Ohkura *et al.* 1995; Paganini-Hill & Henderson 1996). This led to huge optimism that HRT might be used as a disease-modifying therapy, although enthusiasm was tempered by some epidemiological studies failing to find an association (Seshadri *et al.* 2001) or finding association only with very long-term use (Zandi *et al.* 2002b). Trials of HRT, both naturalistic and randomised and controlled, have proved negative (Mulnard *et al.* 2000; Thal *et al.* 2003).

Other risk factors: ethnicity, depression and diet

Historically, although AD is common in many different ethnic groups, it was always said to be rare in black African peoples. Hendrie's group have made careful studies of prevalence and incidence of AD in African-Americans and Nigerians, showing a much lower incidence in those living in Africa. It must be said that genetic, cultural and environmental diversity is at least as large between African nations as between black and white people and so there are likely to be many differences between African-American and Nigerian

people that go beyond the environmental differences (Hendrie *et al.* 2001). Nonetheless, this suggests that a low incidence of dementia in Africa may be due to some protective factor.

Prior depression has also been found to be a risk factor for AD (Jorm *et al.* 1991; Speck *et al.* 1995; Steffens *et al.* 1997; Jorm 2000). Jorm and colleagues identify six possible mechanisms for this association (Jorm 2000), none of which can be confidently excluded. Perhaps the explanation needing fewest radical speculations is the one that depression represents a very early prodromal symptom.

Aluminium was once thought to be associated with dementia but, with the exception of the very high aluminium load in early kidney dialysis (before the use of chelating agents), this association has largely been excluded, although not before a great deal of anxiety was caused to relatives and people worried about AD. Dietary intake of vitamin C or vitamin E has been raised as possible risk factors but the results from epidemiology are inconsistent (Engelhart *et al.* 2002; Luchsinger *et al.* 2003). It may well be that only trials will determine whether these antioxidants offer any protection. Fish oils are suggested to be protective (Kalmijn *et al.* 1997; Morris *et al.* 2003a), whereas polyunsaturated fats increase risk (Morris *et al.* 2003b). In animals a diet rich in cholesterol induces amyloid plaque formation, cholesterol levels alter the processing of the APP protein, and lowering cholesterol levels using statins may be a useful approach to AD therapy in humans for the future (Crisby *et al.* 2002; Petanceska *et al.* 2002; Morris *et al.* 2003a).

Mild cognitive impairment

Mild cognitive impairment (MCI) is a term that has achieved considerable prominence and attention. It has long been clear that there is a group of individuals who are somewhat impaired but who do not have a full dementia syndrome. The difficulty with nosology has been what impairment means: impaired in relation to all adults, young adults, age-matched controls? And for any of these, how much impairment does there need to be for an individual to be considered 'not normal for age'? Attempts have been made to group these people in various categories, including benign senescent forgetfulness, age-associated memory impairment, and others. However, it has been the formulation of MCI by Petersen *et al.* (2001a) that has become widely accepted. Criteria for MCI vary somewhat and are not as established as criteria for the various dementia conditions. However, common to all criteria are (i) that the patient should not meet criteria for dementia; (ii) that there should be some report of cognitive impairment by either the patient or an informant; (iii) that there should be objective evidence of cognitive impairment or decline; and (iv) that there should be no substantial evidence of functional impairment. Some criteria refine these elements, suggesting for example that objective

evidence for cognitive impairment should be a score more than 1.5 standard deviations away from age-adjusted norms. Other refinements include the distinction between amnesic (memory only) and other MCI and between single- and multi-dimensional MCI (Winblad *et al.* 2004). However, one of the difficulties common to all criteria relates to the upper-level criteria that the patient should not have dementia. Oftentimes this will be a question of clinical judgement and it is readily apparent that whether a patient receives a label of MCI or mild AD depends to a large degree on the inclinations of the clinician and specifically how diligently functional impairments are sought and what weight the clinician places on these. While there are excellent scales and measures for assessing function in more advanced dementia, doing the same in very early dementia is difficult and rests entirely on a careful, detailed and sometimes lengthy history. Often functional impairment is specific to an individual and is both culture and gender bound. While one person's functional impairment may be manifested in restricted use of the full capability of a washing machine, another's may be inability to rewire the machine. At least for currently elderly cohorts this example illustrates a probable gender bias and neither functional impairment is detectable without considerable effort. When combined with very mild cognitive impairment and other features, some clinicians would give a diagnosis of dementia; others would not.

This difficulty with diagnostic categories possibly explains some of the discrepancies in the literature on outcomes of MCI. In a systematic review we found rates of conversion to dementia ranged from 2% to 30% per year (Bruscoli & Lovestone 2004). However, diagnostic differences did not seem to account for all this substantial variability. When considering a variety of variables that might account for these different conversion rates, the one that stood out was the origin of the subjects of the study. Where subjects were recruited from a community-based study annual conversion rate was 7.5%, but where subjects were recruited from clinics the conversion rate was significantly different at 15%, despite apparently identical diagnostic criteria. It seems that there is something about people who manage to negotiate the care pathway to a memory clinic that is different from those people identified with the same symptoms in the community. It is likely that the care pathway acts as a selective filter, favouring people with early dementia because they, their carers or their primary physicians recognise the seriousness of the condition in a large proportion of individuals. The task, not yet completed, for researchers is to identify what this factor is.

Various attempts have been made to identify biological factors that might help to predict which people with MCI are more likely to convert to dementia. *APOE* status does predict a higher conversion rate in some but not all studies and promising data have been produced for CSF measures of AD-related proteins and a variety of imaging techniques

(Blennow 2004; Bruscoli & Lovestone 2004; De Leon *et al.* 2004; Maccioni *et al.* 2004; Chong *et al.* 2006). However, none of these findings are yet fully replicated and suitable for use in the clinic.

Nonetheless, despite problems with nosology and with the difficulty in distinguishing people with MCI who progress compared with those who do not, MCI is now a widely used concept in both clinical and research settings. Guidelines recommend that patients should be screened for MCI and monitored for conversion to dementia (Petersen *et al.* 2001b). In the research arena MCI has become the focus for some clinical trials, as preventing conversion from MCI to dementia might indicate that a drug had not only symptomatic effects but disease-modifying or preventive benefits.

Pseudodementia

While some patients in the memory clinic have clear and unarguable cognitive impairment but do not quite meet the criteria for dementia, others have questionable cognitive impairment and yet have sometimes received the diagnosis of dementia. A concept used only rarely today is that of pseudodementia, indicating a patient who appears demented but is not, perhaps because of depression or some other condition. Careful clinical examination is usually sufficient to make a distinction.

Vascular dementia and vascular cognitive impairment

Concepts of vascular dementia have undergone considerable revision in the last two to three decades. The recent history of this revision and the various consensus groups that have attempted to refine our understanding of vascular dementia is reviewed by Román *et al.* (2004). It is now widely understood that vascular pathology coexists with other forms of pathology in many, if not most, cases of dementia. The coexistence of vascular pathology and AD pathology in particular is common and, to complicate matters, both occur to a substantial degree in elderly people without known dementia (Fernando & Ince 2004). There is an inherent problem in disentangling these relationships. Alzheimer's pathology, vascular pathology and cognitive impairment are all common in the elderly and all are likely to coexist as a consequence, quite apart from any mechanistic relationship between pathological processes. Trying to understand which process is important in individual patients in life is extremely problematical. Even with the power of modern imaging, determining the vascular damage to the brain at a sub-stroke level is difficult in life and so researchers are left with post-mortem studies that attempt to extrapolate backwards to determine the relationship between pathology and early symptoms. These difficulties go some way to explaining the currently somewhat confused understanding of vascular dementia.

Nonetheless, it is clear that vascular disease does impact on cognition and four broad categories are emerging: multi-infarct dementia, small-vessel disease, post-stroke dementia and specific vascular dementia syndromes (e.g. CADASIL). These are discussed in turn but it should be understood that there is considerable overlap and that a categorical distinction between types of vascular dementia is inherently problematical. In an attempt to move on from the preconceptions and confusions associated with the term 'vascular dementia', O'Brien *et al.* (2003) have introduced the concept of *vascular cognitive impairment* (VCI), a term that encompasses all forms of cognitive impairment related to vascular disease in the brain. It remains to be seen whether this term will replace 'vascular dementia' in either clinical or research uses.

Multi-infarct dementia

Multi-infarct dementia is perhaps the most widely used category of vascular dementia and to a large degree the category on which diagnostic criteria are built. Clinically it is found with almost equal frequency in males and females, with perhaps a slight excess in males. It usually begins during the late sixties and seventies, although well-confirmed examples are occasionally seen in patients in their forties.

Arteriosclerosis may be obvious in the peripheral and retinal vessels and hypertension will frequently be present, be long-standing and may be severe. Attempts have been made to define the clinical characteristics of multi-infarct dementia but the evidence linking these symptoms with a specific pathological pattern is not overwhelming. The onset is frequently more acute than in AD, and a substantial number of cases only come to medical attention after a frank cerebrovascular accident has occurred. When the onset is gradual, emotional or personality changes may antedate definite evidence of memory and intellectual impairment. Other common early features include somatic symptoms such as headache, dizziness, tinnitus and syncope, which may be the main complaints for some considerable time. Once established the cognitive impairments characteristically fluctuate in severity and progression is said to be stepwise. Apoplectiform features punctuate the progress of the disorder and are due to episodes of cerebral infarction. Commonly they consist of abrupt episodes of hemiparesis, sensory change, dysphasia or visual disturbances. At first they are transient and followed by gradual restitution of function, but later each leaves more permanent neurological deficits in its wake. Each episode may be followed by an abrupt increase in the severity of the dementia. Lacunar infarcts may lead to a variety of neurological defects, including ataxia, dysarthria and motor and sensory disturbances, culminating in the picture of pseudobulbar palsy (dysarthria, dysphagia and emotional incontinence) together with bradykinesia and *marche à petit pas*.

Other features that suggest multi-infarct dementia include the patchy nature of the psychological deficits that result. Thus the basic personality may be well preserved until late in the disease, whereas in other dementing illnesses this is undermined from an early stage. Capacity for judgement may persist for a surprisingly long time, and a remarkable degree of insight is sometimes retained. As a result the patient often reacts to awareness of his decline by severe anxiety and depression. Other emotional changes include lability, no doubt due to lesions in the basal parts of the brain, and a tendency towards explosive emotional outbursts. Episodes of noisy weeping or laughing may occur on minor provocation, often without accompanying subjective distress or elation.

Perhaps the most reliable distinguishing characteristic of multi-infarct dementia is the course it pursues. This is rarely smoothly progressive as in AD, but typically punctuated by abrupt step-like progressions. Acute exacerbations are sometimes followed by improvement for a time, and in the early stages at least, periods of remission may last for months at a time. These features depend on the pathogenesis of the disorder in terms of repeated cerebral infarctions.

Birkett (1972) found that neurological abnormalities predicted arteriosclerosis more accurately than any mental feature. Even in the absence of gross defects, such as dysphasia or hemiparesis, there will often be minor focal signs. The tendon reflexes are often unequal, the plantars extensor or pupil reactions impaired. Parkinsonian features may be conspicuous, likewise evidence of pseudobulbar palsy as described above. Epileptic seizures are found in about 20% of cases, and attacks of syncope are common.

The EEG shows a picture similar to that of AD but the changes tend to be more severe. However, advanced examples can sometimes show normal records. A distinctive feature may be the appearance of focal abnormalities in the region of local cerebral thromboses: a low-amplitude delta focus may emerge if the infarction is sufficiently extensive, and some asymmetry may persist for several weeks thereafter. Frontal delta activity may appear when there are episodes of delirium. Harrison *et al.* (1979) found that the EEG more often showed focal or lateralising abnormalities in patients diagnosed as having multi-infarct dementia than in equivalently impaired patients with AD. The occurrence of paroxysmal activity or of a normal EEG is also commoner in the former than the latter (Erkinjuntti & Sulkava 1991).

Neuroimaging will usually show evidence of cerebral atrophy, sometimes marked in degree. Both old and recent infarctions may be revealed. Multiple small lacunar infarcts will often escape direct detection on CT and the suspicion of vascular dementia should direct the clinician to MRI rather than CT.

The clinical picture of multi-infarct dementia has to a large degree driven the categorical distinctions drawn up to dif-

ferentiate 'vascular dementia' from AD and other dementias. The 'ischaemic index' proposed by Hachinski *et al.* (1975) has been one of the most widely employed as a guide to distinguishing multi-infarct dementia from AD. Features in the clinical history and on examination are given a weighted score as follows: abrupt onset (2), stepwise deterioration (1), fluctuating course (2), nocturnal confusion (1), relative preservation of personality (1), depression (1), somatic complaints (1), emotional incontinence (1), history of hypertension (1), history of strokes (2), evidence of associated atherosclerosis (1), focal neurological symptoms (2) and focal neurological signs (2). Patients scoring 7 or above are classified as having multi-infarct dementia and those scoring 4 or below as having non-vascular dementia, typically AD. The separation of patients on such a basis can be valuable in refining groups for research purposes, and when used with caution can give some guidance to diagnosis in the individual case. However, the index was drawn up on relatively young and mildly affected patients; a very considerable degree of overlap may be expected in the elderly especially when the dementia is more advanced.

The Hachinski index is still often used, although it has largely been superseded in the research context by the semi-operationalised diagnostic criteria drafted by the neuroepidemiology branch of the National Institute of Neurological Disorders and Stroke in association with the Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN) (Román *et al.* 1993). These are summarised in Box 9.2. The NINDS-AIREN criteria sidestep any attempt to define 'mixed' cases of AD and vascular dementia and patients or subjects in research can fulfill both these criteria and the NINCDS-ADRDA criteria for AD simultaneously. These criteria have relatively high specificity but very low sensitivity (Holmes *et al.* 1999).

Small-vessel disease

Evidence of pathology to the vasculature of the brain, falling short of infarct, is common in the elderly and thought to be a major cause of cognitive impairment and indeed dementia. This small-vessel disease is found accompanying AD pathology in one-third or more of those with dementia in the community (Holmes *et al.* 1999) and is probably the major cause of VCI. In small-vessel disease there is evidence of damage to the microvasculature in the brain, demyelination, axonal loss and gliosis (Pantoni & Simoni 2003; Ringelstein & Nabavi 2005).

There are two cardinal features of small-vessel disease: (i) white matter lesions (WMLs), which may be apparent as periventricular lucency (also known as leucoaraiosis) or as deep white matter hyperintensities; and (ii) central grey matter lacunae (Schmidtke & Hull 2005). When first detected on CT, leucoaraiosis was thought to be rare, occurring in some 2% of routine scans on patients with cerebral

Box 9.2 NINDS-AIREN clinical criteria**I Criteria for probable vascular dementia**

- 1** Dementia diagnosed according to defined operational criteria and documented by neuropsychological testing. Among the exclusion criteria are aphasia or major sensorimotor impairments which preclude such testing. Dementia in this context implies cognitive decline from a previously higher level of functioning, whether it has a stable, ameliorating or progressive course. The decline must be manifest in impairment of memory and in two or more other cognitive domains. The resulting deficits must be severe enough to interfere with ADL which are *not* due to the physical effects of stroke alone
- 2** The presence of cerebrovascular disease as detected by focal deficits on neurological examination consistent with stroke (whether or not there is a history of stroke), together with evidence of relevant cerebrovascular disease on brain imaging (CT or MRI). The latter includes multiple large-vessel infarcts, a single strategically placed infarct, multiple basal ganglia or white matter lacunes, or extensive periventricular WMLs. Severity standards are set for excluding trivial infarcts, occasional lacunes or minor periventricular lucencies
- 3** A relationship between **1** and **2** must be manifest, either by onset of dementia within 3 months of a recognised stroke, or by abrupt deterioration or stepwise progression in cognitive function in the absence of a history of stroke

II Clinical features consistent with probable vascular dementia

- 1** Early presence of gait disturbance (*marche à petit pas*, magnetic, apraxic-ataxic or parkinsonian gait)
- 2** A history of unsteadiness and frequent unprovoked falls
- 3** Early frequency or urinary incontinence

- 4** Pseudobulbar palsy
- 5** Personality and mood changes
- 6** Psychomotor retardation, perseveration and difficulty in shifting and maintaining sets

III Features that make a diagnosis of vascular dementia uncertain

- 1** Early onset of memory deficit and progressive worsening of memory and other cognitive functions in the absence of corresponding focal lesions on brain imaging
- 2** Absence of focal neurological signs other than cognitive disturbance
- 3** Absence of cerebrovascular lesions on CT or MRI

IV Clinical criteria for possible vascular dementia

- 1** Dementia with focal neurological signs, but absence of confirmation of cerebrovascular disease on brain imaging
- 2** Absence of clear temporal relationship between dementia and stroke
- 3** Subtle onset and variable course (plateau or improvement) of cognitive deficits and evidence of relevant cerebrovascular disease

V Criteria for definite vascular dementia

- 1** Clinical criteria for probable vascular dementia
- 2** Histopathological evidence of cerebrovascular disease obtained from biopsy or post-mortem
- 3** Absence of neurofibrillary tangles and neuritic plaques exceeding those expected for age
- 4** Absence of other disorder capable of producing dementia

atrophy (Valentine *et al.* 1980). Most of those affected were hypertensive and two-thirds showed evidence of dementia. Zeumer *et al.* (1980) found similar changes in 15 patients, all with progressive dementia and histories of transient, usually recurrent, neurological deficits. All but one were hypertensive and two showed pseudobulbar palsy. Microinfarcts were visible in the basal ganglia in one-third of cases. One of the patients came to post-mortem and showed the histological features of Binswanger's disease. It therefore seemed likely at the time that this might be a neuroradiological marker of the condition. However, with time, growing awareness and the increased use of MRI it became apparent that WMLs are a frequent observation in patients with dementia and in elderly people with memory complaints (Minett *et al.* 2005). They probably represent areas of demyelination resulting from ischaemia. However, their relationship to dementia is disputed. In one community study only 8% of the population were free of WMLs (de Leeuw *et al.*

2001) and the presence of WMLs was predicted largely by mid-life hypertension (de Leeuw *et al.* 2000; van Dijk *et al.* 2004). Not all WMLs are equal and periventricular lucencies in particular appear to be more significantly associated with disease or pathology: periventricular, but not deep white matter, changes are more common in patients diagnosed with AD (Burns *et al.* 2005), and periventricular lesions are more predictive of dementia (Prins *et al.* 2004) and cerebral atrophy than deep white matter hyperintensities (Barber *et al.* 2000). It might be that deep white matter hyperintensities are the result of lifelong vascular damage to the brain – end-organ damage – but it is periventricular lucency that is a marker of VCI. Some evidence in favour of this comes from a study showing that diabetes with and without accompanying hypertension is strongly associated with deep white matter hyperintensities but not periventricular lesions (van Harten *et al.* 2007). Deep white matter lesions may have consequences on the brain beyond dementia

and are associated with depression and motor deficits (O'Brien *et al.* 2003).

The distinction between small-vessel disease and other forms of VCI is as difficult as the distinction between VCI and AD. However, small-vessel disease is most likely to present as a subcortical disorder with a slowly evolving dementia associated with focal neurological deficits, often in hypertensive patients and frequently accompanied by motor signs or other focal neurological deficits. Semi-operational criteria for neuroimaging features (WMLs and lacunae) have been proposed but agreement between raters has been poor and there are no widely accepted imaging criteria in routine clinical use. Schmidtke and Hull (2005) have reviewed neuropsychological deficits in small-vessel disease compared with AD; word fluency and clock-reading appear to have some value in discriminating the disorders.

Binswanger's disease is a subtype of small-vessel disease, previously thought to be rare and first described by Binswanger (1894) under the title 'encephalitis subcorticalis chronica progressiva'. The condition derives from pathological changes affecting the long perforating vessels to the deep white matter and subcortical nuclear masses, resulting in multiple small areas of infarction (lacunes) together with the cardinal feature of diffuse demyelination of the white matter. The arcuate fibres beneath the sulci are by contrast spared, and the cortex itself is substantially intact. The white matter changes are usually extensive, demyelination being associated with pronounced fibrillary gliosis. Possible pathogenic mechanisms include diffuse ischaemia consequent on subacute hypertensive encephalopathy (Caplan & Schoene 1978), or chronic hypoperfusion in the watershed area between the territories of the cortical medullary arteries and the long perforating branches to the white matter (Loizou *et al.* 1981).

Clinical features stressed from the outset were of a slowly evolving dementia associated with focal neurological deficits, usually in hypertensive patients in their fifties or sixties. Caplan and Schoene (1978) clarified the picture from a description of cases proven at post-mortem. They noted persistent hypertension, a history of acute strokes, a lengthy course, and dementia accompanied by prominent motor signs and usually by pseudobulbar palsy. However, the distinctive clinical manifestation was the subacute progression of focal neurological deficits. Such deficits commonly developed in a gradual fashion over some weeks or months, the picture then stabilising with long plateau periods lasting for months or occasionally years. This feature appeared to separate the patients with Binswanger's disease from those whose dementia rested on large-vessel occlusions or on a lacunar state without accompanying white matter demyelination. The dementia varied considerably in its manifestations: some patients showed a phase of ebullience and lack of inhibition, others progressive loss of spontaneity. Memory disorder was not invariably prominent.

Poststroke dementia

The risk of dementia increases substantially after stroke, especially in the elderly. Prevalence studies show up to one-third of those aged above 55 years to have dementia in the 5-year period after stroke compared with a little over 5% of the general population; in a population-based study, the incidence of dementia after stroke was nearly nine times greater than predicted (Mackowiak-Cordoliani *et al.* 2005). The mechanism of poststroke dementia is not understood but is likely to be complex, some patients having strategic infarcts, others multiple infarcts and others with continuing small-vessel disease. Although there is some evidence that hemispheric lesions increase risk of post-stroke dementia, overall the relationship between site of lesion and risk of dementia is not at all clear. In addition to a direct effect of the stroke on brain function, in some patients incipient AD will become apparent after stroke either because cognitive or brain reserve is diminished or because the effects of the stroke make cognitive or functional deficits apparent to the patients themselves or, more likely, to carers.

Specific vascular syndromes

A small number of specific syndromes give rise to a vascular dementia. These include CADASIL, a rare familial disorder that presents with migraine, usually but not always accompanied by aura, recurrent small subcortical infarcts leading to dementia, transient ischaemic attacks and sometimes severe affective disturbance. Neuroimaging reveals white matter abnormalities in subcortical white matter and basal ganglia (Chabriat *et al.* 1995). Onset is typically in the forties, the pedigree will reveal autosomal dominant inheritance and the patient will be free from the typical vascular risk factors (Davous 1998). The disorder is caused by mutations in the *NOTCH3* gene (Joutel *et al.* 1997), which codes for a transmembrane protein involved in complex intracellular signalling and, interestingly, both neuronal development and memory (Louvi *et al.* 2006). Whether either of these functions of Notch proteins are relevant to CADASIL remains to be seen. Identifying families with CADASIL allows pre-symptomatic counselling and testing.

Other genetic disorders also give rise to vascular lesions in the brain. One of the most intriguing of these is hereditary cerebral haemorrhage with amyloidosis (Dutch type), which presents with haemorrhagic strokes and dementia (Maat-Schieman *et al.* 2005). This autosomal dominant disorder results from mutations in the *APP* gene just as in some early-onset FAD. However, the mutation results in decreased A β -42 in contrast to the increase seen in AD and with the AD mutations in the same gene (Bornebroek *et al.* 2003). The primary pathology is cerebral amyloid angiopathy and this is just one of the inherited angiopathies; others include

hereditary cerebral haemorrhage with amyloidosis (Icelandic type) and chromosome 13 familial dementia in British and Danish kindreds (Frangione *et al.* 2001).

Relationship between AD and vascular dementia

Alzheimer's disease pathology and vascular pathology frequently coincide in people with dementia. What is the nature of this relationship? Is it simply common things occurring commonly together or is there a more complex interrelationship between pathologies in the brain that result in dementia? It is unlikely that there is a simple answer to this question that intrigues many researchers in the field. It is possible that there are common risk factors, that AD exacerbates vascular disease, that vascular pathology exacerbates AD or that the two pathological processes are additive in their effects on cognition and function.

There is some evidence for common risk factors. For example, hypertension and diabetes are both *de facto* risk factors for vascular dementia but both are also apparently independent risk factors for AD (Biessels *et al.* 2006; Skoog & Gustafson 2006). The difficulty in disentangling risk factors for AD and vascular dementia in life will be immediately obvious, and there is a certain tautology involved as the presence of vascular risk factors makes a diagnosis in life of vascular dementia more likely and so an association of vascular risk factors with vascular disease is not unexpected. Other common risk factors have been sought including genetic factors. *APOE* variation is strongly associated with both AD and cardiac disease, although there is only conflicting evidence of an association with vascular dementia (Frank *et al.* 2002; Bang *et al.* 2003; Baum *et al.* 2006; Davidson *et al.* 2006) and probably no association with stroke (Sudlow *et al.* 2006). Variation in the gene encoding ACE is probably weakly associated with hypertension and AD, although again there is no reported association with vascular dementia as would be expected if it were a common risk factor (Zuliani *et al.* 2001; Kolsch *et al.* 2005).

The possibility that AD pathological processes might exacerbate vascular disease has not been explored thoroughly but is plausible. As well as amyloid deposition in plaques, congophilic angiopathy representing amyloid deposition in blood vessel walls is a near-universal finding in AD and is the predominant pathology in some families with *APP* mutations (Castellani *et al.* 2004a). In these families haemorrhage is the predominant pathological finding but it is plausible that the thickening of the endothelial wall that accompanies the angiopathy of AD might contribute to ischaemic events and small-vessel disease resulting in a vascular dementia-type pathology. Alternatively, vascular disease may itself initiate or propagate Alzheimer's pathology (Kalback *et al.* 2004; Humpel & Marksteiner 2005) through diverse possible mechanisms all centring on the increased vulnerability of neurones in ischaemic conditions.

Box 9.3 Subtypes of vascular dementia

- I Large or several infarcts (>50 mL loss of tissue): multi-infarct dementia
- II Multiple small infarcts (>3 mm, with minimum diameter 5 mm): small-vessel disease, involving greater than three coronal levels, with hyalinisation, cerebral amyloid angiopathy, lacunar infarcts, perivascular changes
- III Strategic infarcts, e.g. thalamus, hippocampus
- IV Cerebral hypoperfusion, e.g. hippocampal sclerosis, ischaemic anoxic damage
- V Cerebral haemorrhages
- VI Cerebrovascular changes with AD pathology

However, the most parsimonious explanation is that vascular damage to the brain and Alzheimer's pathology are independent processes that have synergistic effects on cognition. Post-mortem studies tend to support this idea, with evidence that the cognitive impairment for a given AD load is greater than expected if vascular disease is also present (Nagy *et al.* 1997; Snowden *et al.* 1997). Such effects might arise from the addition of pathologies in the same brain areas or may be synergistic if they result in dysfunction of different, but interacting, systems.

Neuropathology in vascular dementia

Kalaria *et al.* (2004) have reviewed the various pathological lesions found in vascular dementia and have proposed a set of key variables to be collected at post-mortem and a pathological classification system for subtyping vascular dementia (Box 9.3). These authors note that the commonest lesions are complete infarctions, found in 75% of cases, followed by lacunar infarcts and small infarcts in 50% of cases, cystic infarcts in 25% of cases, cerebral amyloid angiopathy in 10% and haemorrhages in only 2% of cases. Large infarcts, visible to the naked eye, often occur in the watersheds supplied by the major arteries and consist of a core of complete infarction surrounded by a penumbra of ischaemic tissue. A gliosis accompanies infarction and results in scar formation. Lacunae usually result from cavitating infarcts, occurring most frequently in the white matter but may result from haemorrhage. Small-vessel disease takes various forms but all involve damage to the end-arterial wall with hyalinisation, degeneration of the vascular smooth muscle and other changes indicative of arteriosclerosis. Cerebral amyloid angiopathy is the consequence of deposition of aggregated amyloid protein in or near the vessel wall, resulting in thickening and, almost certainly, loss of function.

Epidemiology of vascular dementia

Vascular dementia is common but given the comments above about the difficulties of diagnosis in life and the pitfalls of mixed disease, estimating how common is difficult. Clinically, 15–20% of patients in many series are diagnosed as having vascular dementia, although this is higher (up to 40–50%) in some studies (Kuller *et al.* 2005; Román 2002). However, patients often meet criteria for both AD and vascular dementia, suggesting that pathological studies are necessary. In post-mortem studies of series with dementia also, co-occurrence of pathologies is common and so in order to estimate true prevalence figures population-based pathological studies are needed. A recent meta-analysis found six such studies but these only reinforce the problems in correlating specific pathological findings with clinical syndromes (Zaccai *et al.* 2006). Thus one study found that one-third of subjects had neuropathologically defined AD although the prevalence of clinically diagnosed AD was only 16%. Half of those with AD pathology at post-mortem were not diagnosed with any dementia in life or had vascular dementia and, conversely, one-third of those with clinical AD had insufficient evidence at post-mortem for a definitive diagnosis of AD. All the studies find a high degree of co-occurrence of AD and vascular dementia as do pathological cohorts of people with dementia. At present, the best that can be said is that vascular dementia in all its forms is common, is probably the second most prevalent pathology affecting the elderly with dementia and occurs very frequently together with AD pathology.

The risk factors for vascular dementia are, not surprisingly, evidence of vascular disease, especially in the brain. Past history of stroke, evidence of white matter damage on neuroimaging, hypertension, elevated cholesterol and adverse lipid profile, diabetes and some genetic variants are all risk factors in most studies (Schmidt *et al.* 2002; Kuller *et al.* 2005; Rea *et al.* 2005; Hayden *et al.* 2006; Panza *et al.* 2006). However, it should be noted that in some studies high cholesterol (Mielke *et al.* 2005) and hypertension (Ruitenberg *et al.* 2001c) in late life appears to be protective.

The natural history of dementia is classically described as stepwise or intermittent, especially in multi-infarct dementia. However, the clinicopathological correlation is not strong and slowly progressive dementia also occurs in people with pathological evidence of vascular dementia. A review of the literature suggested that progression of vascular dementia was not distinguishable from that of AD (Chui & Gonthier 1999).

Summary

Vascular dementia is a concept in transition. The concept of vascular dementia as a separate disorder with different clinical profile, different set of risk factors and different pathol-

ogy is no longer sustainable. An attempt has been made to replace the term 'vascular dementia' with 'vascular cognitive impairment', although this seems to sidestep the fundamental problem rather than addressing it. What is clear is that vascular damage to the brain contributes significantly to impairment and to dementia specifically. Vascular damage frequently coincides with AD pathology and trying to disentangle the relative contribution of the two pathologies to functional and cognitive impairment in groups of subjects or in individual patients is exceedingly difficult and may ultimately prove impossible.

However, some concepts have remained valid and useful despite these challenges. It is clear that the separation of vascular damage into small-vessel and multi-infarct types together with cerebral amyloid angiopathy represents a true distinction, although it remains to be seen whether there are many clinicopathological correlations. The concept of vascular risk factors has received a great deal of support and it is clear that vascular risk factors are also, by and large, dementia risk factors although in most cases they are risk factors for both AD and vascular dementia. As the contribution of vascular damage to dementia and as the importance of vascular risk factors becomes increasingly recognised, vascular dementia becomes an ever more important target for therapy.

Dementia with Lewy bodies

Lewy bodies, which are the hallmark of the brainstem pathology of Parkinson's disease, were found relatively recently to occur diffusely in the cerebral cortex and to be accompanied by a dementia syndrome with characteristic clinical features. The nosological status of DLB (previously variously called diffuse Lewy body disease, cortical Lewy body dementia or senile dementia of the Lewy body type) remains a subject of some controversy and its relationship to its allied disorders, AD and Parkinson's disease, is not yet fully understood. DLB is the second or third most common dementia after AD. The frequency in different series varies somewhat from 10% to 20% and whether it is more common than vascular disease depends partly on probable selection biases in post-mortem series and partly on the definitions used for vascular dementia. In any case it is an important cause of dementia.

Clinical features

Males have outnumbered females in some but not all series, with onset typically in the sixties or seventies. Disease duration is on average approximately 10 years but with a wide range (Ransmayr 2000). The classical triad of symptoms of DLB comprises fluctuating cognitive impairment, parkinsonism and visual hallucinations (Byrne *et al.* 1990; Kalra *et al.* 1996; Brown 1999). The fluctuation may be day to day or even hour to hour and may be difficult to distinguish from

delirium. Not infrequently patients have had episodes of admission to medical units for acute confusional states from which they apparently spontaneously recovered before the diagnosis was made. Attention and EEG variability correlate with systematic assessment of fluctuation and although informants sometimes report all dementia patients as showing some variability, the clinical fluctuation is greater in DLB than in other dementia syndromes (Walker *et al.* 2000). The exception is the dementia that occurs in Parkinson's disease which, like DLB, also shows considerable fluctuation in attention (Ballard *et al.* 2002a). A review of studies comparing DLB with AD showed that visuoperceptual and attention-executive impairments were more severe in DLB (Collerton *et al.* 2003).

Visual hallucinations in DLB are complex, often of people or animals, usually undersized and silent, and may not be distressing to the patient. Similar symptoms occur, albeit with less frequency, in Parkinson's disease dementia (Aarsland *et al.* 2001). Psychosis is a common feature of AD also but visual hallucinations are less common in AD than in DLB. Functional neuroimaging suggests that visual hallucinations are particularly associated with hypometabolism in the primary visual cortex together with relatively preserved metabolism in the right temporoparietal association cortex (Imamura *et al.* 1999). The Newcastle group has made a strong case for the fluctuation and psychotic symptoms of DLB to have their origin in a relatively more profound cholinergic deficit relative to AD (Perry *et al.* 1993, 1994; Perry & Perry 1995).

Importantly, hallucinations and delusions occurring early in a dementia syndrome strongly suggest a diagnosis of DLB (Ballard *et al.* 1999a). In fact all the symptoms of DLB are more discriminative relative to AD when found to occur early in the course of the dementia (Del Ser *et al.* 2001). With time, many AD patients become psychotic, have motor symptoms and fluctuation, making clinical distinction from DLB increasingly difficult. In addition, the presence of extrapyramidal symptoms at presentation is highly predictive of Lewy body pathology (Haan *et al.* 2002). Although the presence of symptoms of DLB at presentation is highly predictive of Lewy body pathology, the reverse is not true. In patients with a clinical diagnosis of AD in life but with Lewy bodies found at post-mortem, retrospective assessment of their symptom complex did not show any particular clinical pattern, whether the type of symptoms experienced or indeed the rate of progression (Stern *et al.* 2001).

Parkinsonism occurring after or anteceding dementia by no more than a year is part of the diagnostic criteria for DLB. Rigidity and gait abnormalities are more prominent than tremor, although this can occur. Falls are common (Ballard *et al.* 1999b). The motor manifestations show the typical features of Parkinson's disease, with bradykinesia, rigidity, tremor, mask-like facies and stooped posture. Involuntary move-

ments are sometimes reported, also myoclonus, quadriplegia, dysarthria and dysphagia (Burkhardt *et al.* 1988). Orthostatic hypotension may occur and unexplained losses of consciousness are often seen.

Diagnostic guidelines for DLB, based on the core triad of symptoms (of which two are necessary) and a set of common supportive features, were reached by consensus and then updated (McKeith *et al.* 1996, 1999, 2005). Supportive features include falls, syncope, neuroleptic sensitivity, delusions, non-visual hallucinations, depression and rapid eye movement (REM) sleep disturbance. Notice is especially drawn to the neuroleptic sensitivity. Patients with DLB are highly sensitive to severe extrapyramidal and other adverse effects of these drugs and considerable caution should be exercised in treating psychosis in DLB. Early indications suggested that the accuracy of the consensus diagnostic criteria in relation to post-mortem confirmation was at best modest (Lopez *et al.* 1999), with acceptable levels of specificity but poor sensitivity (McKeith *et al.* 2003).

McKeith *et al.* (1992) described the spectrum of clinical features in detail, making a retrospective case note comparison between 21 cases of DLB and 37 cases of AD proven histologically. The DLB patients tended to show milder cognitive impairment at presentation, and more often showed marked fluctuations at any stage. Episodes of clouding of consciousness occurred in 80% of patients. Visual hallucinations were commoner than in AD, and were often complex, vivid and rapidly moving. One patient saw an express train going through his room, another gypsies climbing through the window. Auditory hallucinations and persecutory delusions were also frequent. The fluctuating nature of such symptoms and their tendency to worsen at night suggested an acute confusional state superimposed on the dementia. Fluctuation was also observed in memory, language and visuospatial abilities; lucid periods with near-normal memory capacity were sometimes recorded until late in the disease. Almost half of the patients with DLB had falls or transient and unexplained losses of consciousness, which were rare in those with AD. Depression was significantly more common in DLB and was sometimes the reason for the initial referral.

Extrapyramidal features in this series were no commoner at presentation than in the AD group, but developed more frequently and more severely later on. An important observation was that they almost always appeared to be directly related to the prescription of antipsychotic medication. Moreover, the patients with DLB appeared to be unusually susceptible to severe reactions to antipsychotics such as chlorpromazine or haloperidol, developing first sedation and then acute onset of rigidity accompanied by postural instability and falls. Rapid deterioration led to death in many cases. There were no such acute reactions in those patients with AD.

Course and outcome

On present evidence it would seem that the clinical course, though widely variable, is shorter than with AD (Olichney *et al.* 1998). In McKeith *et al.*'s (1992) series, the time from onset of symptoms to death was a mean of 1.8 years in the group with DLB and 4.8 years in the group with AD, although others typically find a longer survival time after diagnosis. Those who suffered adverse reactions to antipsychotic treatment fared particularly badly, surviving a mean of less than 1 year. In patients with AD the presence of Lewy bodies and extrapyramidal symptoms predicts a faster decline (Haan *et al.* 2002).

Pathology

At post-mortem the brain usually shows mild cortical atrophy and ventricular enlargement. Pallor is detected in the substantia nigra and locus coeruleus. The distinctive pathological finding is the occurrence of numerous Lewy bodies in the cortex. They are also found in the substantia nigra, other brainstem nuclei and basal forebrain regions, although often less in number than in Parkinson's disease. In Parkinson's disease, occasional Lewy bodies can sometimes be detected in the cortex, but not in anything approaching the numbers seen in DLB.

Lewy bodies consist of rounded eosinophilic inclusions within neurones. They are easily detected in the brainstem, where they stain deeply with haematoxylin and eosin, and where the pale halo around the filamentous core is highlighted by the surrounding neuromelanin. In the cortex, however, they are less eosinophilic and less clearly circumscribed, making their detection less straightforward. The use of anti-ubiquitin antibodies has been an important advance, permitting reliable estimates of Lewy body frequency and proving to be twice as sensitive as conventional stains in revealing them in cortical areas (Lennox *et al.* 1989).

In rare cases Lewy bodies have been found without any accompanying Alzheimer-type pathology (Gurd *et al.* 2000) but this is uncommon (so-called pure Lewy body dementia). The severity of Alzheimer pathology is usually described as well below what would be expected in AD and insufficient to make such a diagnosis on its own. Moreover, the relative distribution of Lewy bodies and Alzheimer pathology do not mirror one another closely. Lewy bodies also occur in AD (Arai *et al.* 2001), even in autosomal dominant AD with known mutations (Rosenberg *et al.* 2000; Lipka *et al.* 2001; Yokota *et al.* 2002). Cortical Lewy bodies in Parkinson's disease are associated with cognitive impairment (Mattila *et al.* 2000).

Varying degrees of cell loss are reported in the cortex, although less severely than in AD. Cell loss is also seen in the substantia nigra and other subcortical nuclei, but less than in

Parkinson's disease. Severe reductions in choline acetyltransferase activity have been found in the temporal neocortex, exceeding even that found in AD (Perry *et al.* 1990, 1993, 1994). Caudate dopamine levels are also depleted, paralleling the neuronal loss in the substantia nigra.

The Lewy body core is composed of aggregates of a protein α -synuclein (Spillantini *et al.* 1997; Hashimoto *et al.* 2004), making DLB one of the synucleinopathies, also including multiple system atrophy, pure autonomic failure and Parkinson's disease itself (Marti *et al.* 2003). α -Synuclein is normally found in the presynaptic compartment and may be important in learning and memory. Mutations in the coding gene have been found to be a very rare cause of familial Parkinson's disease.

Frontotemporal dementia

The term 'frontal' or 'frontotemporal' dementia is used to signify those dementias which depend principally on degeneration within the anterior parts of the brain, as detected by mode of presentation, neuroimaging procedures or post-mortem examination. Some confusion has arisen between Pick's disease, which is properly a neuropathological diagnosis, and FTD, which is a clinical diagnosis. As discussed below, the nosological status of FTD is being clarified by a growing understanding of molecular pathogenesis and the FTDs are best considered as a set of clinical syndromes that show some common features but which have a variety of neuropathological substrates. Pick's disease is one pathological variant of FTD but does not have a typical clinical presentation allowing the pathology to be predicted in life. FTDs are of special importance to psychiatry because of their tendency to present with behavioural disorder and change of personality. In the age range 45–65 years, FTD is an important disorder with an estimated prevalence of 3–15 per 100 000, not very different from that of AD (Bird *et al.* 2003). In some series males predominate and a significant proportion, probably in the range 20–40%, is familial.

Clinical features

The features of FTD are relatively distinct from the other major dementia syndromes and are characterised by change in personality and behaviour accompanied by emotional blunting and apathy and in many cases speech and language deficits (Snowden *et al.* 2002). These symptoms occur in the context of relatively preserved memory, especially visual memory. Features of Klüver-Bucy syndrome are frequently present.

Hodges (2001) describes three distinctive forms of FTD: frontal variant FTD, semantic dementia and progressive nonfluent aphasia. In the Cambridge series, the first two syndromes accounted for 40% each and the progressive

aphasias approximately 20%. Others find frontal variant FTD to be the majority of cases of FTD (Snowden *et al.* 2002). A few cases present as mixed or a very rare clinical variant. Frontal variant FTD presents with classical features of loss of frontal lobe function, specifically orbitobasal structures, namely disinhibition, stereotypy, lack of impulse control and antisocial behaviour. Apathy and loss of executive function resulting in inability to plan are universal but also common in AD and are less useful in differential diagnosis. Compulsive repetitive behaviours or speech patterns are common and Snowden *et al.* (2002) suggest that these behaviours occur more in those with striatal-predominant as opposed to neocortical-predominant pathology; this is in contrast to those with apathy as a dominant syndrome, where the pathology is predominantly frontal. On neuropsychological testing memory is relatively spared but tests of frontal lobe function usually reveal considerable impairment. Hodges (2001) makes the point that many of these tests are particularly sensitive to dorsolateral and not orbitobasal function; nonetheless commonly used neuropsychological tests such as the Wisconsin Card Sorting Test and the Stroop and bedside tests of verbal fluency are useful. Amnesia develops with time but even in relatively advanced dementia, spatial memory can be preserved.

Semantic dementia is, in effect, the temporal variant of FTD and presents with complaints of loss of memory for words but is usually accompanied by a receptive dysfunction that the patient may be completely unaware of. Especially in predominant right-sided atrophy, the semantic loss is frequently accompanied by prosopagnosia, i.e. loss of recognition and naming of faces. Orientation is preserved and, interestingly, where there is memory impairment it is predominantly remote rather than recent memories that are most affected. As might be expected, all tests of verbal cognition are affected but categorical naming tests (naming of defined lists, e.g. animals, in a given time period) are especially so. At least in the mild to moderate stages, patients will perform normally on tests of executive function and non-verbal problem-solving tasks such as Raven's Progressive Matrices.

Non-fluent progressive aphasia presents with speech dysfluency and word-finding difficulties often accompanied by deterioration in spelling (Mesulam 2001). Comprehension is relatively preserved but patients eventually develop global cognitive decline accompanied by profound language difficulty and early autism. This progression may be very protracted. Patients can have only primary verbal defects for 10–15 years (Mesulam 2001). In contrast to semantic dementia and frontal variant FTD, the pathological findings in non-fluent progressive aphasia are very variable and in some instances this is a variant presentation of AD while in others the various FTD pathologies are present. The left temporal lobe is typically preferentially atrophied.

In all FTD variants the onset is usually in the presenile period, with a range from 45 to 70 years (Gustafson *et al.* 1992). There was a small preponderance of males in the series of Neary *et al.* (1988).

A woman of 42 gradually lost her interests and became inefficient at work. She complained of stomach pains for which no cause could be found. Some months later she began repetitive checking behaviour and counting rituals and became progressively untidy and withdrawn. The following year it was apparent that her memory was impaired and her verbal fluency was poor, although she still remained fully orientated. Two years later she was withdrawn, incontinent and mostly mute. She sat swaying and rocking, often singing in a fatuous manner. Marked frontal atrophy and ventricular enlargement were apparent on CT. The EEG remained normal.

An accountant of 40 showed a 2-year decline in efficiency at work and self-care, and developed severe compulsive behaviour. He would check that the front door was closed up to 10 times per hour. A diagnosis of obsessional neurosis was made, although it was noted that insight was lacking. His mood tended to be jovial. During the following year he developed child-like behaviour with yelps and shouts, and became gluttonous, often stealing from other people's plates. When seen 4 years from onset new learning was poor but he gave the dates of past events correctly. He was orientated for place and year but was wrong for the month. He performed very poorly on proverb interpretation. The EEG was normal, but CT showed severe frontal atrophy.

Neurological examination typically shows no abnormalities, other than the emergence of primitive reflexes such as grasping, pouting or sucking. The plantar reflexes may be extensor. Fascicular twitchings are sometimes observed, and some patients develop dysarthria and dysphagia. Late in the disease the patient may become immobile through akinesia and rigidity.

The EEG is usually normal, even late into the disease, in marked contrast to all other forms of dementia and this can be a useful and relatively specific diagnostic marker. Brain imaging may show atrophy largely confined to the fronto-temporal regions, usually with ventricular enlargement. Functional brain imaging, particularly hexamethylpropyleneamine oxine single-photon emission computed tomography (HMPAO-SPECT), can have special importance in revealing diminished blood flow or metabolism selectively affecting the anterior brain regions, even when structural scans show little abnormality.

A professional man of 44 had been suspended from work because of poor performance and certain errors of judgement over the preceding year. A neurologist suspected early dementia, but other consultant neurologists and psychiatrists considered him to be normal. It was thought that the problem might lie with over-critical colleagues rather than with himself. His wife, however, described a gradual change of personality, with rigidity of habits and a tendency towards irritability and agitation. On occasion he had been embarrassing in social situations, making insensitive comments of a personal nature to casual acquaintances. She described marked lacunae in his distant memory, for example for a holiday they had taken some years ago. He admitted to memory problems but in other respects considered that he was well.

Examination showed normal mood and he made good rapport. He was fully orientated and well informed about

recent events, but seemed totally amnesic for significant episodes from his past life. He made occasional paraphasic errors and his verbal fluency was poor. Physical examination showed no abnormalities. The EEG was normal, and CT showed only marginal abnormalities over the left sylvian fissure and possible dilatation of the left anterior horn. These were considered to be of doubtful significance. However, SPECT showed clear evidence of hypoperfusion over both frontal lobes.

Follow-up over the next 2 years showed very gradual deterioration, with increasing lack of initiative, disinhibition and obsessionality. Psychometric testing revealed increasing naming difficulties and problems with card sorting. His mother had suffered from a slowly progressive dementing illness of a similar nature.

FTD-related conditions

Progressive supranuclear palsy and corticobasal degeneration (CBD) are both now considered to be related to FTD (Boeve *et al.* 2003). This change in their nosological status came about because of findings from pathology: all are tauopathies. However, CBD in particular also shows some clinical overlap with common if not universal cognitive difficulties, particularly frontal lobe deficits and the difficulties of speech and language typical of FTD (Graham *et al.* 2003). The assessment of speech can be difficult because of complicating dysarthria but it is clear that there is commonly a cognitive aphasia in this condition.

Differential diagnosis

The subtle nature of the behavioural change in the early stages, and the lack of conspicuous cognitive defects, may lead to long delays before the correct diagnosis is made. A personality disorder may be suspected, especially when some life event appears to have provoked the change in demeanour. Other patients are suspected of alcoholism, or of hypomania when there is elevated mood and disinhibition. Agitation and hypochondria may give the impression of an anxiety or depressive state, and compulsive features may lead to the diagnosis of obsessive-compulsive neurosis. It is not uncommon for the patient to have received treatment for such disorders before the organic nature of the illness becomes evident through progressive lack of self-care and the advent of clear cognitive deficits.

Huntington's disease may be suspected when personality change and psychotic features are prominent, and especially when other family members are affected. Differentiation from AD will rarely be difficult, though occasional patients

with AD present with behavioural change and with anterior rather than posterior hypoperfusion on SPECT. Some cases of FTD are accompanied by motor neurone disease.

Pathology

The gross appearance of the brain at post-mortem is of generalised atrophy combined with striking circumscribed shrinkage of certain lobes, most commonly the frontal and temporal lobes. In the frontal lobes the orbital surface may be affected alone, and in the temporal lobes the posterior half of the superior temporal gyrus may stand out as relatively spared. The distribution of atrophy varies considerably from case to case, but major involvement of the parietal lobes is unusual and occipital atrophy extremely rare. The gyri are roughened and brownish, often with a characteristic 'knife-blade' appearance. The ventricles are dilated, often with great enlargement of the horn of the lateral ventricle beneath the site of maximal cortical atrophy. The basal ganglia and thalamus also show atrophy, sometimes pronounced in the caudate nucleus, but the cerebellum is usually spared.

There has been considerable reassessment and revision of the pathological features of FTD and associated diseases in recent years following the discovery of mutations in the *TAU* gene in one variant, frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17). It is now recognised that many (but not all) cases of FTD, Pick's disease, PSP and CBD share tau-positive pathology (Neary *et al.* 1998; Neary 1999; Munoz *et al.* 2003; Kertesz & Munoz 2004). The critical pathological distinctions are between the presence and absence of inclusions and the type of tau pathology where present. Three main pathological subtypes constitute the majority of cases. Microvacuolar is the commonest and features a superficial layer spongiform change (extracellular

in contrast to the intraneuronal spongiform changes of the transmissible encephalopathies) caused by neuronal loss, a relative absence of gliosis and absence of intraneuronal distinctive lesions. In contrast, in the Pick's type of pathology there is profound gliosis, an absence of spongiform change and there are swollen neurones with tau- and ubiquitin-positive inclusions. Pick bodies are specific inclusions. In the third and least common pathological presentation, microvacuolar change is accompanied by features of motor neurone disease. In all cases the gross pathology is of atrophied temporal and frontal lobes.

Tau is a microtubule-associated protein normally expressed in axons (Avila *et al.* 2004). In AD, the distribution of tau within the neurone changes. Early in the disease, in fact in the prodromal phase before the onset of clinical dementia, tau is apparent in a soluble and hyperphosphorylated state in cell bodies in neurones and then, as the disease progresses, in neurofibrillary tangles. In the FTDs, tau-positive inclusions are found in neurones and glia, although these inclusions do not have the same morphological appearance as neurofibrillary tangles in AD. However, as in AD, tau is aggregated, relatively insoluble and highly phosphorylated relative to normal adult tau. There are six isoforms of tau in human adult central nervous system, all expressed by differential splicing of a single gene (D'Souza & Schellenberg 2005). The isoforms differ by having three or four microtubule-binding domains (3R or 4R) and none, one or two N-terminal inserts of unknown function. The relative predominance of the different isoforms differs in the various FTDs and associated disorders. Thus 3R tau predominates in Pick's disease and 4R tau in CBD and PSP. Some cases have no tau lesions but do have lesions that stain with antibodies to ubiquitin. Ubiquitin is a protein that is tagged to proteins to target them for degradation.

Some cases of FTD are inherited in an autosomal dominant fashion whereas others are apparently sporadic. Familial cases of not only FTDP-17 but also more common variants of FTD have been found to have mutations in the *TAU* gene (Heutink 2000; Pickering-Brown 2004; Goedert & Jakes 2005). Broadly speaking these mutations fall into two classes: (i) those that occur in or near the microtubule-binding domains are likely to affect the normal function of tau; and (ii) those that are in the exon 10 splice site alter the relative expression of 3R and 4R tau (Rademakers *et al.* 2004). As some of the FTDs have an excess of 3R tau and others an excess of 4R tau, it can be assumed that the relative expression of both classes of isoform is more important than the absolute expression. If the normal ratio of 3R to 4R tau is disrupted, or if the tau has a mutation in or close to the microtubule-binding domains, then tau appears to no longer properly bind microtubules but instead aggregates, becomes highly phosphorylated and thereby disrupts neuronal function leading to neuronal loss. The neuronal dysfunction

caused by abnormalities in tau remains to be fully elucidated but evidence from cell and animal studies suggests one important function that is disrupted is axonal transport. Other families with FTD or variants have been linked to chromosomes 3 and 9 and it is likely that the responsible genes will be identified soon.

Distinction between FTD and AD

In FTD changes of character and disposition are often noted from the onset, whereas memory disturbance is almost invariably the presenting feature in AD. Incontinence occurring early in the course of the dementia has also been regarded as indicative of FTD, and may similarly be due to the accent of pathology on the frontal lobes.

Parietal lobe symptomatology in the form of dysphasia, apraxia and agnosia is said to be much less common in FTD than AD, likewise disturbances of gait and other extrapyramidal features. Aspects of Klüver–Bucy syndrome may be detected early in FTD but are generally a late development in AD.

The facile hilarity and asponaneity of Pick's disease has been contrasted with the depressed anxious mood and overactivity of patients with AD, though asponaneity occurs in the latter condition also. The disturbance of circadian rhythms with nocturnal activity that occurs so often in AD is relatively lacking in FTD (Harper *et al.* 2001).

The preservation of a normal EEG, even in the presence of moderately advanced dementia, will suggest FTD, likewise atrophy restricted to the anterior half of the brain as revealed by CT or MRI. However, intermediate pictures will quite often be encountered. SPECT holds the promise of more reliable differential diagnosis.

It appears therefore to be chiefly in the mode of onset of the disorder and in the neurological concomitants that a clinical differentiation is to be sought. The differentiation is more easily made in the earlier than the later stages, since ultimately any differences become submerged.

Huntington's disease

Huntington's disease has attracted a great deal of interest and attention. Choreiform movements are combined with dementia, serving as a clinical marker that has allowed its genetic background to be studied with care. Since Huntington's original account in 1872, cases have been reported from all over the world and no race appears to be immune. Prevalence varies markedly from one investigation to another. Very high figures have been reported from Tasmania, while in parts of Japan the disease appears to be extremely rare. Overall, in Europe, the prevalence is about 4–8 per 100 000 population (Harper 1992), although there are foci of higher prevalence. An astonishingly dense focus is

known to have existed for a long time in the Moray Firth area of Scotland, with the equivalent of 560 cases per 100 000 in a small fishing community on the east coast of Ross-shire (Lyon 1962).

Aetiology

The disease is an autosomal dominant disorder and as a consequence half of the offspring of an affected person can be expected to develop the disorder, with equal incidence in males and females. Cases in Massachusetts and Connecticut have been traced back to emigrants from England, principally to three men and their wives who left from Bures in Suffolk in 1630 and thereafter produced 11 generations of choreics (Vessie 1932). However, subsequent work has cast doubt on some of the genealogies in Vessie's study (Harper & Morris 1991). A family history is not always forthcoming, even among classic examples. This may be the result of several factors: the early death of a parent, illegitimacy, lack of an adequate history, or concealed and circumscribed knowledge within the immediate family circle.

Huntington's disease results from an expansion in the CAG repeat within exon 1 of the gene encoding huntingtin (htt). As CAG is the codon for glutamine, this results in a string of glutamines being incorporated into the protein and Huntington's disease is one of a series of polyglutamine disorders, themselves a subset of the triplet repeat disorders (Koshy & Zoghbi 1997). Myotonic dystrophy and fragile X are examples of triplet repeat disorders caused by non-glutamine triplet repeat expansions; dentatorubral-pallidoluysian atrophy is an example of another polyglutamine disorder. The normal repeat length in the *HTT* gene is 36 or less. An expansion of 40 or more codons causes Huntington's disease, with a correlation between size of expansion and virulence of the disease. Large expansions tend to result in earlier onset of disease (Stine *et al.* 1993) and in some, but not all, studies with more severe neurodegeneration as measured by imaging (Culjkovic *et al.* 1999; Roth *et al.* 2005) or at post-mortem (Rosenblatt *et al.* 2003) or with more rapid clinical decline (Ward *et al.* 2006).

There are a number of features common to diseases resulting from this type of genetic variability, most characteristic of which is the phenomenon of anticipation, whereby there is a tendency for the triplet to expand during meiosis thus resulting in a predisposition to longer repeats in offspring. As the severity of the disorder, as evidenced by its age of onset, is related to the size of the repeat, this translates to a propensity for the disorder to be of earlier onset in children. As the triplet instability is greater in the generation of male gametes, there is also a tendency for the disorder to show increased anticipation in the children of male sufferers (Nance 1997). Juvenile onset is associated with larger expansions, often secondary to paternal transmission. Onset in infants can be a

consequence of massive expansion of the triplet repeat (Seneca *et al.* 2004).

The mechanism whereby an expansion in the triplet repeat causes Huntington's disease is not fully understood. In animal models expression of the expansion region alone is sufficient to cause disease, suggesting a predominant toxic gain-of-function effect rather than a loss of normal function (Bates & Gonitell 2006; Borrell-Pages *et al.* 2006). These mouse and cellular models have added considerably to the understanding of Huntington's disease and have provided models on which to develop therapeutic strategies. The Huntington's disease repeats tend to aggregate and when these aggregates occur in nuclei this appears to mediate toxicity (Yang *et al.* 2002). Inhibiting the formation of these aggregates *in vivo* reverses toxicity (Kazantsev *et al.* 2002), as does increasing turnover of aggregates by stimulating autophagy (Berger *et al.* 2006). Clearly this is promising, but this is a rapidly advancing field and it is by no means certain that a toxic effect of Huntington's disease aggregates in nucleus, possibly affecting gene transcription events, is the only pathogenic mechanism.

Genetic counselling and presymptomatic testing

Huntington's disease provides an archetypal example of best practice when it comes to the use of genetics in clinical practice. This has been reviewed extensively elsewhere (Simpson & Harding 1993; Scourfield *et al.* 1997; Ensenuer *et al.* 2005). Prior to the availability of direct gene testing, a large proportion of unaffected family members indicated that they would welcome a predictive test but only a small proportion went on to have one (Tyler & Harper 1983; Meissen & Berchek 1987). Persons who do go on to be tested generally do well and psychological well-being measures improve after testing, whatever the result (Bloch *et al.* 1992; Huggins *et al.* 1992; Simpson *et al.* 1992; Wiggins *et al.* 1992; Adam *et al.* 1993). Surprisingly, some of those receiving 'good news' have the worst outcomes (Almqvist *et al.* 2003). This matches with clinical experience: living with a family with Huntington's disease, growing up with a 50% risk, is an experience that dominates individuals' lives. People having presymptomatic testing talk about their lives having been 'put on hold'. For some, having this threat of disease removed or having uncertainty removed is liberating. For others the readjustment to a life of health and removal from the world of disease can be difficult and all people undergoing presymptomatic counselling require extensive support. International consensus has laid out the ground rules for this support: counselling by two professionals, sessions separated by a minimum of 3 months, and results only given in person and only after the parent of the counsellee has received a diagnosis and/or genetic confirmation. Pitfalls in counselling are common and it is essential that such

counselling takes place in the context of clinical genetics units.

Clinical features

The onset is usually in the fourth and fifth decades, with an average in the mid-forties. Variation is wide, however, and onset may occur in childhood and in extreme old age. In general the age of onset among sibs tends to be closer than among members of different families, but the correlation is not sufficiently close to be of much value in genetic counselling. There is evidence that the disease follows a more severe course when onset is early rather than late, also that emotional disturbance is more prominent as a premonitory feature. There is some suggestion of other changes in manifestation with age of onset, striate rigidity predominating in the early twenties, choreic symptoms in middle age and intention tremor after the age of 60. Special features of the disease in childhood are considered below.

Considerable variation may be seen in the relationship between the neurological and psychiatric features. In the typical case involuntary movements precede dementia, although the reverse can also be seen. Occasionally, several years may separate the appearance of the two components, or the two may begin and proceed throughout together. Certainly once both are well established each tends to worsen in conformity with the other.

Very occasionally chorea may be the sole manifestation. Dementia without chorea has similarly been recorded, even when chorea was prominent in previous generations of the family. Other variations include the form the neurological abnormalities take, progressive rigidity with parkinsonism replacing the typical choreic movements in up to 10% of cases. All such variations usually appear sporadically; despite some indications in the literature, it is not well established that in different families the form of the disease tends to breed true.

Presenting symptoms

The presenting symptoms were almost equally divided between neurological and psychiatric features in Heathfield's (1967) survey. Neurological presentations were usually with choreiform movements, or less often with unsteadiness of gait, a tendency to fall or general clumsiness. Psychiatric presentations could be with symptoms of incipient dementia, but even more commonly with change of disposition, emotional disturbance and paranoia. Families with predominant psychiatric symptoms have been reported (Lovestone *et al.* 1996; Tsuang *et al.* 2000; Correa *et al.* 2006), suggesting that there may be risk factors for psychosis in these families independent of the *HTT* gene mutation.

Most observers agree that psychiatric changes are often present for some considerable time before chorea or intellectual impairment develops. A change in personality may be

marked, the patient becoming morose and quarrelsome, or slowed, apathetic and neglectful. These are well recognised as premonitory symptoms by those who have practical dealings with communities in which the disease is relatively common. Paranoid developments may be the earliest change, with marked sensitivity and ideas of reference. Sometimes a florid schizophrenic illness may be present for several years before the true diagnosis becomes apparent. Depression and anxiety may be marked from the outset.

Neurological features

The neurological features often go unrecognised at their first appearance. The typical early choreic movements consist of randomly distributed and irregularly timed muscle jerks, brief in duration and unpredictable in their appearance. At first the patient is merely thought to be clumsy or fidgety. Early movements may be no more than the twitching of a finger, or fleeting facial grimaces that pass for mannerisms. The movements usually start in the muscles of the face, hands or shoulders, or are first manifest in subtle changes of gait. Speech is often affected early with slight dysarthria. For some time the patient may conceal the involuntary nature of the movements by exploiting them to perform some habitual activity such as smoothing the hair or the clothes.

With worsening of the disease the pathological nature of the motor disturbance becomes abundantly obvious. The movements are abrupt, jerky, rapid and repetitive but variable from one muscle group to another. They may be aggravated by voluntary movement but may also occur spontaneously. The face shows fleeting changes of expression and constant writhing contortions that bestow a grotesque appearance. The fingers twitch, the arms develop athetoid twisting movements and the proximal musculature is affected with shrugging of the shoulders. However, it is characteristic that even late into the disease the movements largely cease during sleep.

The gait is sometimes affected by a curious dance-like ataxia that results from the variable choreic influences on the lower limbs: the weight tends to be carried on the heels while the toes are dorsiflexed, and often a foot will remain suspended off the ground for longer than usual. Eventually the patient walks with a wide base, exaggerated lumbar lordosis, wide arm abduction and zig-zag progression due to lurching of the trunk. Progress is interrupted by pauses and even backward steps, and accompanied by a great increase in choreiform movements of the upper limbs. Hemichorea, massively affecting one half of the body, may be seen. Involvement of the diaphragm and bulbar muscles may lead to jerky breathing, explosive or staccato speech, dysphagia and difficulty in protruding the tongue.

In addition to such involuntary movements, Folstein *et al.* (1986) emphasise a characteristic disorder of voluntary activity that can be an important aid to diagnosis. The rhythm and speed of fine motor movements is disturbed, with

conspicuous slowness in the performance of tasks. Disturbances of eye movement have also been reported, often from early in the disease and with gradual worsening over time. Patients have difficulty in initiating fast saccades when asked to glance quickly at objects in the periphery, also impairments of smooth pursuit and gaze fixation (Quarrell & Harper 1991).

In some patients extrapyramidal rigidity may be present, or spasticity with pyramidal signs. As mentioned above, some cases develop striate rigidity rather than chorea, perhaps especially when the onset is at an early age (the so-called Westphal variant). This is commonly associated with akinesia, tremor and cogwheel rigidity, and occasionally progresses to torsion dystonia. Fits are more frequent in this variety than in the generality of cases (16% compared with 3%) (Myrianthopoulos 1966).

Dementia

The cognitive impairment is commonly insidious in development. Brandt and Butters (1986) and Folstein (1989) summarise the studies that have sought to characterise the dementia in detail. General inefficiency at work and in the management of daily affairs is usually the presenting feature, rather than obvious memory impairment. A prevailing apathy, setting in early and impeding cognitive functioning, has been stressed as characteristic (McHugh & Folstein 1975). In consequence the patient's performance on everyday tasks is usually more slipshod than psychological testing would predict during the early stages of the disorder. Executive dysfunction is present and correlates with caudate atrophy (Peinemann *et al.* 2005). Overall, in early disease, the pattern is of decreased attention, executive dysfunction, and deficits in immediate memory with relatively preserved general cognition, semantic memory and delayed recall memory (Ho *et al.* 2003). Executive dysfunction is interesting in that patients show deficits in planning but not execution of tasks (Watkins *et al.* 2000).

Slowing of cognitive responses is usually marked from an early stage. Rigidity is observed in thinking and behaviour, with difficulty in changing easily from one activity to another. Memory impairment can usually be demonstrated when carefully sought, even in patients examined within a year of onset of the chorea (Butters *et al.* 1978). However, it is rarely conspicuous as in AD, and it gradually becomes submerged in general difficulties with attention, concentration and organisation of thought. The relative sparing of memory as the disease progresses is consonant with the pathological finding that the limbic areas of the brain are often less affected than in other dementing processes. Disorientation in time and place tends similarly to be a late development.

Detailed investigation into the nature of the memory deficits shows certain distinctive features as outlined by Brandt and Rich (1995). Thus the predominant difficulty appears to lie with deficient retrieval strat-

egies rather than acquisition deficits, in that free recall can be markedly impaired in the presence of near-normal multiple-choice recognition. The retrograde amnesia is usually severe and generalised, being equally impaired across the decades and not showing the temporal gradient of Korsakoff's syndrome. This again reflects impaired retrieval processes. However, recognition as well as recall deficits are observed and a meta-analysis of the literature suggests that both make substantial contributions to the episodic memory deficits in the disease (Montoya *et al.* 2006a).

With regard to implicit (procedural) memory, there is an interesting difference from the deficits seen with AD; lexical priming is well preserved (e.g. on word-stem completion tasks) while the acquisition of motor and perceptual skills is impaired. This pattern is the reverse of that seen in AD, probably reflecting the accent of neuronal loss in the basal ganglia.

Focal psychological features are also rare in comparison with other primary dementias (Bruyn 1968; McHugh & Folstein 1975). Word-finding difficulties can occur, and verbal fluency is severely affected from the early stages, but dysphasia, dyslexia, apraxia and agnosia are seldom detected. However, tests of visuospatial functioning are typically poorly performed. Judgement is often severely impaired as part of the widespread intellectual decline, but insight is commonly retained for a considerable length of time. The patient may thus be aware of his mental changes, complaining that he feels dulled, slow and forgetful and that his thinking is muddled.

These clinical impressions were confirmed by Aminoff *et al.* (1975), who examined 11 patients with the disease an average of 6 years after onset, and when all were sufficiently impaired to have warranted premature retirement from work. The intellectual deterioration was found to be global, with a pattern of results on psychometric testing which approximated to that of the decline normally occurring in old age. Memory was not selectively impaired, and no patient showed focal symptoms such as dysphasia or dyspraxia. Of the 11, seven were fully orientated for time, place and person, and nine retained full insight into their condition.

Distractibility is a marked and characteristic feature, and can be seen as the counterpart of the disturbed motor patterns. Depression may be severe, especially while insight is retained, and suicide is a considerable risk in the early stages. Eventually, however, the mood is of apathy or fatuous euphoria, and inertia and self-neglect become pronounced. Episodes of restlessness and irritability or outbursts of excitement may occur from time to time, and some patients become difficult to manage on account of spiteful, quarrelsome or violent behaviour. A picture resembling akinetic mutism may mark the terminal stages.

The special features of the dementia in Huntington's disease – poor cognitive ability generally but a lack of language disorder or other focal cortical deficits – has suggested that it owes much to subcortical rather than cortical pathology. The pronounced apathy that accompanies and develops

along with it is also typical of subcortical dementia. In line with this, apathy but not depression accounts for some of the variance in episodic memory and other cognitive deficits in early Huntington's disease (Baudic *et al.* 2006). Dementia is usually a relatively late symptom but exceptions are recorded where it is the predominant presenting symptom (Cooper, D.B. *et al.* 2006).

Affective and psychotic disturbance

Affective and psychotic features become obtrusive in many cases, often early in the course or even preceding the onset of chorea or dementia. Most common symptoms are dysphoria, agitation, irritability, apathy and anxiety (Paulsen *et al.* 2001a). Major depressive illness is frequent, sometimes recurrent and can be responsive to drugs or electroconvulsive therapy. A schizophrenic or paraphrenic picture may also be seen. Delusions of persecution can be pronounced, with religiosity and sometimes grandiosity. Ideas of reference are perhaps accentuated by the attention attracted by the involuntary movements and bizarre facial expressions.

Folstein *et al.* (1983) surveyed the incidence of affective disorder among 88 patients (from 63 kindreds) drawn from a defined geographical area in Maryland; 41% showed major affective disorder, 32% being depressive and 9% bipolar. This development had antedated the Huntington's disease by 2–20 years in almost two-thirds of cases. Moreover, it appeared to be confined to certain families, suggesting that the association may represent genetic heterogeneity within Huntington's disease. Five probands with affective disorder and five without were subjected to detailed family studies; affective disorder accompanied the Huntington's disease significantly more often in the families of the former than the latter, and was also somewhat commoner among unaffected family members. Suicide had already been stressed by Huntington (1910), and has been found to account for 7% of deaths among non-hospitalised patients (Reed & Chandler 1958).

The schizophrenia-like pictures can also be an early development. McHugh and Folstein (1975) prefer the term 'delusional-hallucinatory states', noting the emergence of psychotic symptoms from a pervasive delusional mood. They describe the typical progression as follows: the patient is overwhelmed by a vague impression of an uncanny change in reality which becomes laden with meaning of an uncertain nature. Delusions and hallucinations distil from this, often welling up suddenly and usually lasting several months. Treatment with neuroleptics can lead to considerable improvement. McHugh and Folstein suggest that the admixture of dementia with such a picture may account for many of the reports of severe personality change and paranoid features among patients with Huntington's disease.

Behavioural change

Change of behaviour and/or personality was noted in 42% of 65 patients identified in the Oxfordshire region (Watt &

Seller 1993). Aggression and violence, usually against the spouse, was the most common change, followed by suspiciousness and outbursts of temper. Aggression was particularly common among men and quarrelsomeness among women.

Preclinical changes

Autosomal dominant conditions offer the opportunity to unambiguously study the very earliest symptoms, as family members carrying the mutation can be identified and studied in detail prior to obvious manifestation of disease. For Huntington's disease the relatively preserved age of onset within families and correlation with expansion length allows particularly detailed phenotypic studies at around the time of expected onset. In one very large study, preclinical symptoms included anxiety, paranoid ideation and psychoticism in one cluster of subjects and depression in another (Marshall *et al.* 2007). Neuropsychometric testing shows deficits in memory prior to executive dysfunction and motor speed in preclinical mutation carriers (Robins Wahlin *et al.* 2007). Berrios *et al.* (2002) found evidence for cognitive deficits but not personality or mood changes when comparing carriers with non-carriers in families with Huntington's disease and make the case that being part of a family with such a disease is itself highly stressful. They conclude that cognitive dysfunction is likely to be due to biological effects and personality or mood changes to psychological mechanisms. Some of these cognitive impairments are detectable more than 2 years before disease onset (Paulsen *et al.* 2001b); in line with this, functional imaging shows changes, notably diminished activation of the left anterior cingulate cortex, in presymptomatic subjects (Reading *et al.* 2004).

Investigations

Electroencephalography characteristically shows poorly developed or complete loss of alpha rhythms. There may be generalised low-voltage fast activity or random slow activity, but this too may disappear as the disease progresses. In consequence the record may become entirely flat. Occasionally, however, a normal record may be obtained even in the presence of advanced dementia.

Computed tomography and MRI show dilated ventricles, often particularly affecting the frontal regions. Atrophy of the heads of the caudate nuclei may be clearly apparent, with loss of the normal convex bulging into the lateral walls of the frontal horns. Various linear measures have been proposed for establishing this feature as an aid to diagnosis, but they are not sufficiently specific to be of value in the individual case (Shoulson & Plassche 1980). In addition MRI studies have shown significant reductions in the thalamus and the medial temporal lobe structures (Jernigan *et al.* 1991).

Functional imaging techniques can be of particular value by revealing marked hypometabolism in the caudate and

putamen. Using PET, Kuhl *et al.* (1982, 1985) showed that this developed early in the disease and before tissue loss was evident on CT. In contrast, metabolic values were often normal in other brain regions despite severe disability and CT evidence of atrophy. Caudate hypometabolism was also observed in occasional subjects at risk of Huntington's disease, even while they were asymptomatic. Mazziotta *et al.* (1987) confirmed this in a large group of at-risk persons; 31% showed bilateral reductions in caudate glucose metabolism, which was close to the 34% estimate for the likelihood of developing the disease when age and other factors were taken into account. Smith *et al.* (1988) and Gemmell *et al.* (1989) showed that reductions of cerebral blood flow may be detected with SPECT in the caudate nuclei in a large proportion of patients. This, being more widely available, is likely to find clinical application in uncertain cases.

A recent systematic review of imaging studies in Huntington's disease showed that both structural and functional imaging has demonstrated striatal and cortical atrophy that correlates well with cognitive deficits (Montoya *et al.* 2006b), suggesting that the complex cognitive deficits in Huntington's disease that accompany the motor disorder result from abnormal connectivity between the basal ganglia and the cortex.

The value of PET in remedying a false diagnosis of Huntington's disease was illustrated in a woman of 55. For the past 10 years she had shown a slowly progressive dementia, along with increasing motor disorder by way of a stiff unsteady gait, writhing of the hands and choreiform movements of the face. The antecedent family history was at that time uncertain, but her sister in New Zealand was known to suffer from an entirely similar illness. The motor disorder in both cases had been judged to be typical of Huntington's disease. The EEG showed moderate diffuse theta and occasional delta waves.

However, CT showed well-preserved caudate nuclei, despite very pronounced cortical atrophy and ventricular dilatation. Her sister's scan was remarkably similar. Doubts about the diagnosis were further reinforced when vigorous efforts to trace the family history revealed longevity in the parents and their many siblings, with no evidence of dementia or movement disorder in any of them. The parents proved to be first cousins.

It was therefore concluded likely that the illness represented a recessively inherited dementing disorder, with adventitious movements attributable to the neuroleptics that had been administered for many years. In confirmation that Huntington's disease was unlikely, PET showed excellently preserved metabolism in the caudate nuclei, but with poor metabolism in both frontal lobes and both thalami.

Course and outcome

The course after the first definitive manifestations is generally much longer than with other primary dementing illnesses. The average duration is reported as 15–20 years, but with wide variation, some cases showing very slow progression over several decades.

Special features in childhood

Huntington's disease may occasionally set in during childhood or adolescence, although the true diagnosis will sometimes only be made at post-mortem. In several respects the disease tends to differ from the adult form, yet the pathological changes at post-mortem are the same (Hayden 1981; O'Shea & Falvey 1991). Muscular rigidity and tremor are commoner than choreiform movements, the mental deterioration tends to be rapid, and epileptic fits occur in more than half of the cases. The time to death is generally much shorter than with adult cases.

After developing normally the child begins to fail at school and shows difficulties with concentration. Change of personality and anxiety are common. He may become clumsy, ataxic and dysarthric. The absence of chorea readily leads to other diagnoses even in families known to harbour the disease. Friedreich's ataxia may be suspected, or Wilson's disease or postencephalitic parkinsonism. When a change of personality is the predominant manifestation, this may all too easily be ascribed to external factors, especially when the onset is at the approach of adolescence.

A 25-year-old man was admitted to hospital for the mentally handicapped. He was judged to have low intellect and to suffer from a personality disorder. He showed ataxia, tremor, dysarthria and muscular rigidity, but these were thought to be due to the neuroleptics he had been given. He was illegitimate and the fate of his father was unknown. His mother insisted that he had been a bright and inquisitive child, and that until the age of 11 he had progressed well at school. From then on he had shown unwillingness to work and increasingly aggressive behaviour. On leaving school he obtained simple labouring jobs, and was repeatedly arrested for thefts and other misdemeanours. From 18 he became increasingly withdrawn and developed dysarthria. During several hospital admissions thereafter he had been variously regarded as psychopathic or mentally subnormal, and was treated with a variety of neuroleptics. At 22 he was arrested for indecent exposure and other sexual offences.

Psychometric assessment was difficult, but he obtained an IQ equivalent of 67 on the coloured progressive matrices, compared with a verbal reasoning score of 103 recorded when he was 11. Detailed review 2 years later showed a parkinsonian gait, dysarthria and markedly increased tone in the limbs. There were jerking tremors around the mouth and in the fingers of the left hand. He spoke only monosyllabically, but proved to be fully orientated in time and place.

EEG revealed the absence of alpha rhythm and a very low amplitude tracing. CT showed flattening of the heads of the caudate nuclei (Fig 9.6). Over the next few weeks he declined abruptly, and post-mortem brain examination showed the typical pathology of Huntington's disease (Brooks *et al.* 1987).

Fig. 9.6 Autopsy appearances of a patient with Huntington's disease, confirming shrinking of the heads of the caudate nuclei. Reproduced from Brooks, D.S., Murphy, D., Janota, I. & Lishman, W.A. (1987), *British Journal of Psychiatry* **151**, 850–852.

It has been known for some time that 'juvenile-onset' cases, i.e. those setting in before the age of 20, are more likely to demonstrate paternal than maternal transmission. For example, Osborne *et al.* (1982) found that children with onset before the age of 10 had an affected father approximately four times as frequently as an affected mother. This puzzling feature now finds an explanation from recent discoveries in molecular genetics.

The death rate of children in the first decade is known to be high in families with Huntington's disease, and has often been vaguely ascribed to 'mental deficiency' or 'spinal paralysis' (Oliver & Dewhurst 1969). The infant mortality is also high, and Oliver and Dewhurst suggest that this may be partially due to undiagnosed cases occurring even in infancy. Such deaths are often attributed to birth injury, spasticity or quadriplegia. However, social factors are also likely to be important in contributing to the infant mortality, since families with Huntington's disease are often disadvantaged and sometimes severely disorganised (see below).

Other psychiatric associations

The frequent occurrence of change of personality and emotional disturbance as premonitory symptoms of the disease has already been mentioned, also the marked psychotic features which may accompany the dementia. The association with severe depressive illness may have special genetic determinants. In addition, certain other psychiatric associations deserve emphasis.

A large number of psychiatric abnormalities, sometimes severe in degree, are reported when detailed studies of families with Huntington's disease are undertaken. Some fami-

lies are severely disorganised on account of a multitude of pathologies, involving both the patients themselves and their relatives. Epilepsy, schizophrenia, mental defect and a variety of other degenerative brain diseases have been reported. How far these may represent common genetic determinants remains to be established. It is possible that to some extent assortative mating between patients from Huntington families and those with other physical and psychiatric handicaps may contribute to the frequency of such disabilities.

Minski and Guttmann (1938) noted a variety of psychopathological features in the relatives of cases, particularly a personality characterised by explosive irritability and readiness to take offence. Suicide has been reported to be frequent even among members unaffected directly by the disease (Bickford & Ellison 1953). It is unclear how far this may be due to endogenous mental illness or the result of knowledge of the consequences of the condition. Watt and Seller (1993) found that one-third of first-degree relatives of patients gave a history of depression, mainly reactive to stresses within the family or to the onset of definitive illness in a family member. No support was obtained for a direct pathogenic effect of the Huntington gene in leading to depression or to personality disturbance in as yet unaffected persons.

In a study of 102 patients, Dewhurst *et al.* (1970) vividly illustrate the psychosocial consequences of the disorder: 10 attempted suicide and 13 self-mutilation; 19 were alcoholics and 18 had had convictions for serious criminal offences. Of those who had married, 38% subsequently divorced or separated, usually because of social or intellectual deterioration in the patient. Sexual disturbances were common: excessive demands, sexual assault, sexual deviation, impotence and frigidity. Notably there was often a history of promiscuity with the production of illegitimate offspring. The children were sometimes found to be at risk from their parents, with examples of serious neglect.

Oliver (1970) showed that unaffected siblings from Huntington families could also become victims of their disturbed environment. Ninety-three out of 150 either died young, became psychotic or suffered such disturbance as psychopathy, chronic alcoholism, criminality or divorce.

Mistakes in diagnosis

Huntington's disease may be mistaken for many other psychiatric and neurological illnesses, certainly in the early stages. Surveys have shown that over one-third of cases may be wrongly diagnosed initially (Bolt 1970; Dewhurst *et al.* 1970).

In a systematic study of patients in Maryland, Folstein *et al.* (1986) found that 11% had been given some other diagnosis, mainly because the existence of a diagnosed family member was not known to their

doctor. Systematic interviewing of relatives revealed 47 cases additional to the 212 already known, and in half of these there had been some other false diagnosis. Moreover, 15% of the 212 cases reported by community physicians proved on review not to have Huntington's disease but to be suffering from other neurological and psychiatric conditions. Sometimes tardive dyskinesia consequent on medication had led to the mistake.

Psychiatric misdiagnoses are the most common, especially a label of schizophrenia or paranoid psychosis. When schizophrenic features are obtrusive, the chorea may readily be ascribed to 'schizophrenic mannerisms' or to the medications given. Affective psychosis, anxiety state and personality disorder may be the initial diagnosis. Other forms of dementia will often be suspected when a family history is not forthcoming, and the motor abnormalities which develop may then be ascribed to dyskinesia induced by phenothiazines.

Bolt (1970) found that diagnoses of neurosis or affective psychosis were almost invariably revised before the patient's death, but sometimes a diagnosis of schizophrenia or paranoid psychosis was not. A diagnosis of some other form of dementia or of neurological disease was much less likely to be corrected.

Neurological mistakes include multiple sclerosis, Wilson's disease, Parkinson's disease, neurosyphilis, cerebellar disorders and ataxia due to drug abuse. Arteriosclerotic or senile chorea may be misleading in the elderly: distinguishing features include the absence of a family history, and mental changes that are less conspicuous or progressive; moreover, these are often vascular in origin and can therefore be abrupt in onset and with a tendency towards resolution. The rare syndrome of *hereditary chorea without dementia* (benign familial chorea) may also be misleading (Quarrell & Harper 1991). This autosomal dominant disorder usually presents in childhood and mainly affects the head, face and upper limbs. In most families there is little progression beyond childhood, although worsening has occasionally been seen throughout adult life (Schady & Meara 1988). Intellect remains unimpaired.

The childhood form of Huntington's disease is liable to be mistaken for mental subnormality, Friedreich's ataxia, Wilson's disease, epilepsy, spasticity or birth injury. Sydenham's chorea may be simulated, but is usually sudden in onset and associated with other rheumatic manifestations.

Whenever the picture of Huntington's disease is atypical, and particularly when seizures, areflexia or muscle wasting are present, neuroacanthocytosis should be suspected. The examination of fresh blood films may then immediately clarify the diagnosis.

Pathology

The brain is usually small and atrophic although this varies greatly in degree. It is generally difficult to correlate the

intensity of pathological changes with the severity of mental symptoms. The frontal lobes are often the site of maximal cortical change. Marked dilatation of the ventricular system is characteristic, especially of the frontal horns, along with striking atrophy of the caudate nuclei. Instead of bulging into the lateral ventricles these may be represented by a mere rim of tissue along the ventrolateral edge of the dilated anterior horns. The putamen is also atrophic, although the globus pallidus usually escapes in large degree.

Microscopic examination shows cell loss accompanied by gliosis. This can usually be detected in the cortex even when atrophy is not severe. It is particularly marked in the frontal lobes. Severe cell loss is invariably present in the caudate and putamen together with much astrocytic proliferation. The loss of small nerve cells is particularly striking. Similar changes of less degree are sometimes found in the globus pallidus, substantia nigra or cerebellar nuclei.

The white matter shows diffuse loss of nerve fibres, often with consequent narrowing of the corpus callosum. Vascular changes are not marked and cannot be incriminated in the pathogenesis of the disorder. The presence of neuronal nuclear inclusions was first highlighted by transgenic animal models and subsequently revealed in the human disease. Formal assessment of intranuclear inclusions using immunocytochemistry can contribute to the accuracy of post-mortem diagnosis (Maat-Schieman *et al.* 2007).

Biochemical studies

Although the genetic mechanisms causing Huntington's disease have been fully explained, the biochemical mechanisms have not and it is far from clear how expansions in the *HTT* gene give rise to neurodegeneration. In post-mortem studies, Perry *et al.* (1973) and others have shown reduced levels of γ -aminobutyric acid (GABA) in the basal ganglia and substantia nigra of brains from patients with Huntington's disease compared with brains from neurologically normal persons. GABA is an inhibitory synaptic transmitter, so its lack could be significant in relation to the movement disorder. Subsequently, a marked reduction in the enzyme responsible for the synthesis of GABA (glutamic acid decarboxylase, GAD) in the putamen and globus pallidus was demonstrated (Bird *et al.* 1973; Bird & Iverson 1974). Levels were normal in the frontal cortex, thus indicating a selective loss of GABA-containing neurones from the basal ganglia. It is now known that GABA receptors are depleted in the striatum from early in the disease, and before there is extensive cell loss and atrophy (Walker *et al.* 1984).

Cholinergic neurones are also severely deficient in the striatum, as reflected in low levels of choline acetyltransferase and of cholinergic receptors. In contrast, the dopaminergic system is spared (Spokes 1980). Indeed dopamine (and noradrenaline) have proved to be elevated in the striatum and substantia nigra, perhaps as a consequence of the low

GABA levels since GABA inhibits the release of dopamine in the nigrostriatal system.

A model was therefore proposed whereby the intact nigrostriatal pathway in Huntington's disease releases approximately normal quantities of dopamine onto a considerably reduced population of striatal neurones, leading to net dopamine overstimulation of those that remain (Spokes 1980; Marsden 1982). Dopamine overactivity in the striatum is known to provoke chorea. This could therefore be the key neuropharmacological feature of Huntington's disease, at least where the movement disorder is concerned; a similar excess of dopamine in the mesolimbic system may underlie the behavioural manifestations and psychoses seen with the disease.

In addition to neurochemical abnormalities and possible excitotoxic insults, there is evidence for oxidative stress and mitochondrial abnormalities in Huntington's disease (Browne & Beal 2006; Trushina & McMurray 2007). The mitochondrial toxin 3-nitropropionic acid (3NP) induces a Huntington's disease-like disorder in experimental animal studies, and both neurochemical and imaging investigations in these animals suggest that mitochondrial toxicity might combine with *N*-methyl-D-aspartate (NMDA)-induced excitotoxicity to induce neuronal cell damage (Lee & Chang 2004; Brouillet *et al.* 2005; Perez-De la Cruz & Santamaria 2007). In people with Huntington's disease, neurones bearing NMDA receptors are lost early and NMDA agonists, like 3NP, recapitulates some aspects of the disease in animal models, adding weight to this combined excitotoxicity/mitochondrial abnormality hypothesis (Fan & Raymond 2007).

Finally, it is remarkable how many neurological disorders have aggregated, relatively insoluble, protein inclusions. Huntington's disease joins AD, DLB, CJD, Parkinson's disease and others in this respect (Lovestone & McLoughlin 2002). Two protein machineries are responsible for clearing 'unwanted' proteins in both the aggregated and non-aggregated state: the ubiquitin-proteasome system and the process of autophagy. A defect in either or both has been postulated as an 'upstream' or primary cause in various of these diseases. For Huntington's disease, the evidence from model organisms and cells that there might be a defect in autophagy is strong (Ravikumar & Rubinsztein 2006; Rubinsztein *et al.* 2005) and might suggest novel therapeutic possibilities.

Prion diseases

The prion diseases, also known as the transmissible spongiform encephalopathies (TSEs), comprise a group of disorders of humans and other mammals, some of which are important causes of primary neurodegenerative dementias including CJD, Gerstmann-Sträussler-Scheinker disease (GSS) and fatal familial insomnia (FFI). These disorders are characterised neuropathologically by vacuolation, astrogliosis, neuronal loss and aggregation of a proteinaceous infec-

tious particle or *prion*. Aguzzi and Polymenidou (2004) review the history of research of these disorders, noting that scrapie (a TSE in sheep) was described in the nineteenth century and that the transmissible nature of the condition was demonstrated in the 1930s. The first disease in humans to be described as a TSE was Kuru, a disorder of indigenous peoples in Papua New Guinea resulting from ritualistic cannibalism. This was the lifework of Gajdusek who was also the first to demonstrate that CJD was also transmissible to non-human primates. The prion disorders became an urgent and pressing public health concern when in the late 1980s there was an epidemic of a TSE in cattle in the UK (bovine spongiform encephalopathy, BSE) and then in the late 1990s when a variant of CJD in humans was first described and then shown to have arisen from BSE (Ironside 2003). These concerns are receding as an epidemic in humans has not occurred, although the risk has not disappeared (Manson *et al.* 2006). Nonetheless, two decades of intense research has yielded the most extraordinary body of work that has described a novel aetiology of disease and one that, for a time, challenged the very bedrock of biological understanding (Glatzel *et al.* 2005).

Prion biology

Arguably, the central dogma proposed by Watson and Crick (DNA to RNA to protein) has had two major challenges: the discovery of reverse transcriptase (RNA to DNA) by Temin, Dulbecco and Baltimore in 1970 and the demonstration by Prusiner in the early 1980s that characteristics, in this case disease, can be passed from one organism to another by proteins alone (Prusiner 1982). Placed in this context it is easy to see why the prion-only hypothesis of the TSEs has been subjected to such a thorough critique. Nonetheless, it has withstood this and is accepted, almost unanimously, by those in the field although there remain many unanswered questions.

The endogenous prion protein (PrP^c) is a normal protein, highly abundant in neurones and believed to be involved in copper metabolism, oxidative balance and neuroprotection (Cui *et al.* 2003; Roucou *et al.* 2004; Leach *et al.* 2006). PrP^c contains a high proportion of α -helices but can undergo conversion to a tertiary structure with more than 40% β -pleated sheets. This form, known as PrP^{Sc}, tends to form insoluble aggregates as do other β -pleated peptides (e.g. A β of AD). However, in this case, the β -pleated PrP^{Sc} has two apparently unique characteristics: it is almost completely resistant to degradation by proteases and can interact with native PrP^c and promote its conversion to PrP^{Sc}. It is this second characteristic that confers the infectious property on prions.

However, the process whereby PrP^{Sc} initiates pathogenesis *in vivo* remains controversial. One view is that the pathogenic process can be initiated by a single pathogenic molecule that converts a normal endogenous molecule to a pathogenic

form, which in turn converts further endogenous molecules, thus setting off a train of events resulting in massive conversion of endogenous PrP^c and thus disease. The initiating event might be exogenous protein (iatrogenic TSE or variant CJD in humans; probably BSE in cattle), a random event in a genetically prone animal (scrapie in sheep, sporadic CJD in humans), or a mutation massively increasing conversion to PrP^{Sc} (GSS, FFI or familial CJD). An alternative view is that a balance normally exists between a pool of PrP^{Sc} and PrP^c, albeit heavily weighted to PrP^c. A small shift in this balance, it is suggested, might lead to a nucleation event with the formation of small amounts of aggregated PrP^{Sc} and this nucleus would act as a seed for further conversion of PrP^c to aggregated PrP^{Sc}. A further view is that PrP^c is in equilibrium with an intermediate state that interacts with a chaperone before aggregating with PrP^{Sc} (Fasano *et al.* 2006). All these ideas are variants of the prion-only hypothesis but determining the precise mechanism of pathogenesis is obviously important for therapeutics.

The prion-only hypothesis generates a number of predictions all of which have turned out to be true. Thus, for example, it was predicted that as infectivity was dependent on protein–protein interactions, then as PrP is not identical in all species there would be some species specificity in infectivity and this seems to be true: infectivity is far more virulent within a species than between species (Baron 2002; Moore *et al.* 2005). Similarly, as infection is postulated to result from an interaction between exogenous and endogenous protein, then it was predicted that animals lacking the endogenous protein would be resistant and this too turns out to be the case (Bueler *et al.* 1993; Weissmann & Flechsig 2003). Most strikingly, altering the host gene confers a different pattern of disease. Thus normal mice show much longer incubation times when infected with hamster scrapie than when infected with mouse scrapie. However, the situation is altered when transgenic mice are artificially created by the introduction of the hamster prion gene (Prusiner *et al.* 1990; Prusiner 1991; Prusiner & DeArmond 1991). Incubation times for hamster scrapie are then dramatically reduced. In elegant experiments the converse has also been shown to occur. In other words, the relative species barrier can be broken by genetic manipulation of the host prior to infection.

Surprisingly, however, given the wealth of research and the huge advances that have been made in understanding infectivity, little is known about the mechanism whereby PrP^{Sc} accumulation induces neurodegeneration. It is not depletion of PrP^c because animals lacking the protein show little or no ill effects (Bueler *et al.* 1993). Nor is it simply accumulation of PrP^{Sc}, as chronic accumulation of this protein in the absence of PrP^c is also harmless (Brandner *et al.* 1996). It seems most likely that the intracellular location of PrP is critical and that translocation from the endoplasmic reticulum to the cytosol or perhaps a transmembrane location underlies neurotoxicity (Aguzzi & Polymenidou 2004; Harris 2003).

The prion gene

Further molecular genetic studies have concentrated on the prion gene (*PRNP*) itself. This has emerged as abnormal in many patients suffering from CJD or GSS. In a family with CJD, Owen *et al.* (1989) found a mutation consisting of a 144-bp insertion in the prion gene, and Hsiao *et al.* (1989) found a point mutation at codon 102 in two families with GSS. The potential pathogenicity of such mutations was clearly demonstrated by Hsiao *et al.* (1990); transgenic mice created to carry the codon 102 mutation spontaneously developed spongiform degeneration some 5–6 months later.

The *PRNP* gene is highly conserved between species and has a simple structure, consisting of three exons only, with the open reading frame contained entirely within the second of these. An N-terminal repeat region of a nonapeptide followed by four octapeptides is the site of variation in the number of repeats but not a site for normal or pathogenic point variation. There are such variants elsewhere in the gene, including those mutations causing familial TSEs (Mead 2006). These autosomal dominant disorders (CJD, GSS and FFI) have been associated with more than 30 different mutations in *PRNP*, resulting in a premature stop codon, an amino acid substitution or the insertion of an octapeptide repeat. There is a degree of genotype–phenotype correlation in these familial TSEs (discussed below). In addition to variants or mutations causing autosomal dominant TSEs, there are a number of common polymorphic variants, mostly SNPs in the gene, some of which alter susceptibility to the disease. Most notable of these is that at codon 129, which might code for either methionine or valine (M129V). This variant has a strong influence on susceptibility, with homozygosity to the 129V variant conferring increased risk of both sporadic and iatrogenic CJD (Collinge *et al.* 1991; Palmer *et al.* 1991). To date all variant (v)CJD cases have been homozygous for 129M, although there has been one heterozygous patient reported as having preclinical vCJD; this individual had received blood from a donor with CJD and had extensive evidence of prion protein accumulation in the peripheral lymphoreticular system but died of unrelated causes (Zeidler *et al.* 1997a; Peden *et al.* 2004). The phenotype of the disease is also affected by the genotype, with homozygous 129M individuals showing classical clinical presentation of sporadic CJD whereas presentation with slower progression, absence of myoclonus and absence of the typical EEG findings were associated with other genotypes (Parchi *et al.* 1999).

The finding of susceptibility variants raises the possibility that different populations may have intrinsically different risk of CJD as the variant frequencies show marked differences across ethnic groups. Thus the 129M allele frequency is approximately 0.65 in the UK, higher in Africa and higher still in Japan where 129V is rare (Mead 2006). This is an example of a gene–environment interaction, oft searched for but rarely found; another SNP in *PRNP* (E219K) shows a

similar effect in influencing susceptibility (Shibuya *et al.* 1998). Other susceptibility loci may exist and are being actively sought in both humans and in animal models.

Epidemiology of CJD

A relatively short time ago CJD was held to be a rare disorder with even rarer familial forms and the occasional clustering. A review of cases in France over a 15-year period to 1982 found a frequency of less than one case per million, of which 6% were familial (Brown *et al.* 1987). Clusters of CJD have been reported worldwide but in some instances are likely to be due to chance occurrence of more than one case in the same area (Cousens *et al.* 1999; Beaudry *et al.* 2002), in other instances to be due to familial disease (Chapman & Korczyn 1991), and in yet other cases remain unexplained and might be due to an environmental effect, possibly exogenous prion exposure (Arakawa *et al.* 1991; Cousens *et al.* 2001; Mad'ar *et al.* 2003).

However, the epidemic of BSE in the UK has raised the possibility of a substantial change in the frequency of TSEs. The epidemic in cattle peaked in 1992 and over 180 000 animals have developed the disease, with very many more likely to have been slaughtered in the preclinical phase (Anderson *et al.* 1996). Dairy farmers claim to readily identify cattle in the early phases of disease with subtle changes in behaviour, especially in the milking parlour (Anon, personal communication). Strict control was introduced on the feeding of cattle, with ruminant protein being banned as feed first for ruminants and then any farmed animal. Peaks in BSE also occurred in other countries in Europe and North America and controls were also introduced outside the UK. These control measures have almost eliminated TSEs from the UK cattle herd, although occasional cases still do occur. Scrapie is of course endemic but sheep to human transmission is not thought to have occurred. Chronic wasting disease is a TSE disorder of deer and is also common, occurring in up to 10% of the farmed population, but it too has not been shown to have crossed the species barrier although concerns remain.

Variant CJD was first described in 1996 and then shown to be linked to BSE by strain typing in mice and by biochemical approaches (Manson *et al.* 2006). In March 2007 there were 165 cases of vCJD known to the national CJD surveillance unit (<http://www.cjd.ed.ac.uk/>). All reported cases are homozygous for 129M. This raises the possibility that 129VV homozygotes or 129MV heterozygotes may have carrier status and may succumb or be themselves capable of transmitting disease. Evidence in favour of this concerning scenario came from studies of appendices which showed two 129VV individuals who were asymptomatic but who had extensive PrP accumulation (Ironside *et al.* 2006), as well as from the individual referred to above who had evidence of PrP accumulation following infected blood transfusion and

who was 129MV (Peden *et al.* 2004). Given these concerns, the long-term impact of BSE and other TSEs in farmed animals on the population remains to be seen.

Iatrogenic TSEs result from the accidental transfer of PrP from one individual to another during a medical procedure. Originally this was thought to occur only with the direct transfer of neuronal material, either through tissue use or a neurosurgical procedure. There was an outbreak of CJD following the use of pituitary-derived growth hormone and gonadotrophins (Brown 1988), and transmission was also shown to occur with corneal and dural transplants (Lang *et al.* 1998), resulting in disease with a slightly different clinical presentation. More recently, concern has been raised regarding blood and other non-neural tissue transfer as it has become increasingly realised that PrP deposits occur extensively in the lymphoreticular system, even though pathological expression is limited to the nervous system (Aguzzi & Glatzel 2006; Ironside 2006).

Clinical features of CJD

The clinical features of sporadic CJD are very diverse. Both sexes appear to be equally affected, although a female preponderance has sometimes been reported. The onset is usually in the fifth or sixth decade but cases are reported with onset at any adult age. A prodromal stage is usually described, lasting weeks or months and characterised by neurasthenic symptoms. The patient complains of fatigue, insomnia, anxiety and depression, and shows a gradual change towards mental slowness and unpredictability of behaviour. Occasionally the mood is mildly elevated with loquacity and inappropriate laughter. Already at this stage there may be evidence of impaired memory and concentration, the limbs may appear to be weak and the gait unsteady. Frequently, however, objective findings are lacking and a 'functional' psychiatric disorder is suspected. This is especially likely in patients in whom the early symptoms remit for several weeks at a time. In a review of sporadic CJD cases sleep disturbance, anxiety and psychosis were the commonest symptoms and psychiatric symptoms in general occurred in 80% of patients in the first 3–4 months of illness (Wall *et al.* 2005).

An instructive example was reported by Keshavan *et al.* (1987).

A 38-year-old man became forgetful and disorientated from Christmas 1983, but this was attributed to heavy alcohol consumption and depression. His marital situation and business affairs had become chaotic. When admitted to a psychiatric hospital 6 months later his mental state showed marked fluctuations, with disorientation and bizarre memory disturbances alternating with periods of lucidity. He was emotionally labile and gave approximate answers

to questions, and the presumptive diagnosis was of hysterical pseudodementia.

In August 1984, EEG showed mixed theta and delta activity, attributed to possible alcoholic encephalopathy, but CT was normal. No abnormal neurological signs could be detected apart from a pout reflex and a shuffling gait. During the following month he deteriorated markedly and became regressed in his behaviour. In October he was referred for a further opinion, at which stage it was impossible to test cognitive functions because of extreme distractibility. He was perplexed, gazed vacantly and spoke in a slurred incoherent babble. At this stage neurological examination revealed gross apraxia, generalised myoclonic jerks and choreoathetoid movements. He was incontinent of urine and faeces. CT now showed some evidence of atrophy, and EEG showed prominent slow waves maximal over the left frontotemporal region. He then followed a downhill course until his death in March 1985, when post-mortem confirmed the diagnosis of CJD.

Intellectual deterioration or neurological defects soon become prominent. The latter are extremely variable but are liable to involve motor functions, speech or vision. Myoclonic jerks are almost invariably seen. There may be ataxia of cerebellar type, spasticity of limbs with progressive paralysis, extrapyramidal rigidity, tremor or choreoathetoid movements, depending on the brain regions principally involved. Involvement of the anterior horn cells of the cord may lead to muscular fibrillation and atrophy, especially of the small hand muscles, resembling amyotrophic lateral sclerosis. Speech disturbances are common with dysphasia and dysarthria, likewise parietal lobe symptoms such as right-left disorientation, dyscalculia and finger agnosia. Vision may be severely affected with rapidly progressive cortical blindness. Apart from this, sensory changes are usually absent. Brainstem involvement may lead to nystagmus, dysphagia or bouts of uncontrollable laughing and crying. Epileptic fits may occur.

Attempts have been made to classify this bewildering variety of phenomena but with little success. A given case may show a succession of different neurological features as the disease progresses. A broad classification into those which begin with cerebellar symptoms and those with parietal lobe symptoms has been suggested, similarly into cases with and without spinal cord or visual cortex involvement.

Intellectual deterioration follows or appears along with the neurological defects and evolves with great rapidity. An acute organic picture may be present initially, with clouding of consciousness or frank delirium. Auditory hallucinations and delusions may be marked, and confabulation is often seen. Ultimately a state of profound dementia is reached,

accompanied by gross rigidity or spastic paralysis and often a decorticate or decerebrate posture. Repetitive myoclonic jerking of muscle groups is often still evident late in the disease. Emaciation is usually profound by the time death occurs.

Considerable effort has been expended in identifying a diagnostic test for CJD with most attention being paid to markers in CSF. Both 14-3-3 protein and tau are elevated and show modest sensitivity and specificity in diagnosis (Geschwind *et al.* 2003; Van Everbroeck *et al.* 2003; Castellani *et al.* 2004b). CT may show cortical atrophy and ventricular enlargement but this is rarely gross in degree. Indeed, CT can be essentially normal when the dementia is well advanced, a feature that was suggested to be of some importance in differential diagnosis (Galvez & Cartier 1984). The use of MRI has been of more value in diagnosis and prognosis of CJD. Increased grey matter signal in sporadic CJD is associated with shorter survival (Urbach *et al.* 1998) and diffusion-weighted imaging shows high specificity and sensitivity for both diagnosis and prediction of clinical course (Shiga *et al.* 2004; Young *et al.* 2005). Most notably, however, the MRI finding of a bilateral pulvinar signal (the 'pulvinar sign') is very highly sensitive and specific for vCJD (Zeidler *et al.* 2000; Collie *et al.* 2001).

Electroencephalography is almost always markedly abnormal (Wieser *et al.* 2006). A variety of changes have been reported and different findings may emerge at different stages of the illness. Initially there is some diffuse or focal slowing. Later, paroxysmal sharp waves or slow spike-and-wave discharges appear; these are bilaterally synchronous and may accompany the myoclonic jerks. Ultimately, a characteristic pattern emerges of synchronous triphasic sharp wave complexes at 1–2 Hz, superimposed on progressive suppression of cortical background activity. The triphasic discharges are at first intermittent, but evolve to a periodic picture at rates of 1–2 Hz. The latter changes may be helpful in diagnosis, though usually only late in the course of the disease.

The course is much more rapid than with most other primary dementing illnesses, the great majority of patients dying within 2 years. Death is usually preceded by a period of deepening coma that lasts for several weeks.

Pathology

The brain may appear to be somewhat atrophied but often there is little abnormal to detect macroscopically. Histological examination shows great variability from case to case, but the essential features consist of neuronal degeneration, great proliferation of astrocytes and a characteristic spongy appearance of the grey matter. In some varieties the latter may be so pronounced that it is visible to the naked eye. The degenerated neurones often show an accumulation of lipid material.

The accent of the pathology may fall on different regions, accounting for the various clinical pictures that are seen. The cortex is nearly always involved, although often with relative sparing of the parietal and occipital lobes. The hippocampus may also escape. In different cases there may be a marked emphasis on the corpus striatum, thalamus, cerebellum, substantia nigra, brainstem and spinal cord. The corticospinal tracts and also the extrapyramidal pathways are often severely degenerated.

The 'status spongiosus' of the cortex is highly characteristic, showing as finely meshed vacuolation under the microscope. The vacuoles then enlarge and coalesce to form microcysts (Lantos *et al.* 1992; Bell & Ironside 1993). Severely affected areas have the appearance of being riddled with tiny cavities. In some varieties this is widely disseminated. Electron microscopy shows the presence of vacuoles within the cytoplasm of neurones and astrocytes, particularly within dendrites, and the accumulation of abnormal cytoskeletal protein. Status spongiosus is not entirely pathognomonic for CJD, having occasionally been reported in SDAT, Pick's disease, Wilson's disease and other degenerative conditions.

There are usually no senile plaques or neurofibrillary tangles as in AD, no massive circumscribed atrophy as in Pick's disease, and no evidence of an inflammatory reaction. However, some cases show extracellular amyloid plaques especially in the cerebellum. The cerebral vessels appear healthy, or if cerebrovascular disease is present this appears to be incidental. Immunocytochemistry using antibodies to prion protein gives a positive reaction, which can be useful diagnostically in uncertain cases.

Variant and familial forms of CJD

Variant CJD was first described in 1996 by Will *et al.* and shows both clinical and pathological differences from sporadic CJD (Stewart & Ironside 1998; Collinge 1999). The onset is much earlier, typically in young adults, and course is more rapid. The onset is usually with neuropsychiatric symptoms including depression, anxiety and behavioural changes (Zeidler *et al.* 1997b). This is followed rapidly by cerebellar ataxia and myoclonus, followed later by cognitive deterioration and ending in a prolonged period of akinetic mutism. A small proportion of patients (<10%) may present with cerebellar ataxia at outset (Cooper, S.A. *et al.* 2006). The neuropathology is also distinct, showing florid amyloid plaques surrounded by vacuolation (Will *et al.* 1996).

Familial CJD is rare but shows some genotype–phenotype correlations. Thus families with the octapeptide repeat and those with G114V and H187R mutations show notably early neuropsychiatric symptoms and/or personality problems (Mead 2006). Mead (2006) reviews this phenotypic variability and correlation with mutation and notes that families with the E200K mutation present with rapidly progressive dementia with myoclonus in their late fifties, with those also having 129M homozygosity showing a unique PrP deposit

in the cerebellum. On the other hand, families with the octapeptide repeat show a high degree of phenotypic variability, with age of onset from 21 to 82 years and a very highly variable clinical presentation, disease course and neuropathological findings.

Other TSEs

Gerstmann–Sträussler–Scheinker disease is an inherited TSE also resulting from mutations in the *PRNP* gene. It is rare, with a frequency of 1–10 per 10 million population (Liberski & Budka 2004). It typically presents with progressive ataxia, extrapyramidal symptoms, dysarthria and dementia and has an early age of onset, usually in the fourth or fifth decade (Collins *et al.* 2001). The average disease duration is 7 years and the neuropathology includes elements of the TSEs such as spongiform change and astrocytosis, as well as features of AD as there are, in many cases, neurofibrillary tangles (Ghetti *et al.* 1994) and amyloid plaques. The tangles are composed of the same protein (tau) as in AD, but the plaques are predominantly PrP.

Fatal familial insomnia is also a *PRNP* mutation disorder. Interestingly, the mutation D178N in the gene results in FFI when codon 129 codes for methionine but results in CJD when codon 129 codes for valine. The clinical picture is of disruption in circadian cycles resulting in insomnia, dysautonomia and motor dysfunction (Benarroch & Stotz-Potter 1998). On examination there may be chronic hypertension and loss of nocturnal decrease in blood pressure. Laboratory studies show hypercortisolism together with elevated catecholamine levels and abnormal rhythms of growth hormone, prolactin and melatonin. Neuropathological findings include severe thalamic degeneration.

Assessment and differential diagnosis

Every patient suspected of a primary dementia requires comprehensive evaluation. This will in all cases require certain investigatory procedures in addition to the routines of history-taking and clinical examination. It is commonly held that the principal aim must be to exclude a remediable cause for the patient's symptoms and that the diagnosis of AD is one of exclusion. However, truly reversible causes of dementia are rare, vanishingly so in the elderly, and although important to be alert to the possibility, a specialist in old age psychiatry may never see such a case. Nor is it true that the diagnosis is one of exclusion: AD, the commonest dementia, has a characteristic presentation and can be confidently diagnosed following a careful clinical evaluation. Diagnosis is important because it carries with it prognostic information, treatment options and is highly valued by families and carers. A full evaluation is important not only to assess the primary disorder but also other concomitant disorders that may still be aggravating the situation and will sometimes

have caused the patient to present at this particular time. Indeed cognition is profoundly affected by physical illness even in those without dementia, and treating systemic illness improves cognition even to the point of changing patients below the threshold for dementia on screening scales to the normal range (Inouye *et al.* 2006; Milosevic *et al.* 2007). This is important but in most cases a thorough evaluation would readily distinguish between the physically ill with cognitive symptoms and those with a primary dementia.

Conditions amenable to treatment include pathologies within the skull such as cerebral tumour, subdural haematoma, normal-pressure hydrocephalus and general paresis, also certain systemic disorders that may be impairing cerebral function indirectly. These indirect impairments include the several causes of cerebral anoxia, myxoedema, hypoglycaemia, metabolic derangements due to renal or hepatic disease, vitamin deficiencies, alcoholism, and intoxication due to various drugs and chemicals. The tendency, especially in the elderly, for a depressive illness to masquerade as dementia or to aggravate its manifestations must also be remembered. However, depression presenting in late life can be prodromal for dementia and even apparent dementia reversing with resolution of depression (pseudodementia) turns out not to be a benign condition as 5 years later the majority will have an established dementia (Saez-Fonseca *et al.* 2007).

The proportion of patients that appear not to have dementia at all has been reported as relatively high in an early series of reports of consecutive series of suspected dementia cases, largely early onset and mostly admitted to neurological units (Marsden & Harrison 1972; Victoratos *et al.* 1977; Smith & Kiloh 1981). In these series some 15% of the patients were judged not to be demented after full evaluation, but to be suffering from some other organic psychosyndrome or from non-organic psychiatric disorder. Tumours and normal-pressure hydrocephalus were not infrequent in these series. Among the eight tumours in Marsden and Harrison's series three were benign, three had no abnormal neurological signs and seven showed global impairment of intellect without focal psychological deficits. Non-organic psychiatric disorder masquerading as dementia was common in the UK and Australian series, and amounts to 8% of cases overall. Depression is most often responsible. In discussing such results, Wells (1978) concludes that potentially correctable disorders (depression, drug toxicity, hydrocephalus, benign intracranial masses) may be expected in some 15% of patients, with an additional 20–25% in whom some useful intervention will be possible (control of hypertension, withdrawal of alcohol or genetic counselling).

More recent reports confirm a substantially different rate of non-degenerative and non-vascular dementia in early-onset versus late-onset cases. In a large study from the Rochester Epidemiology Project, of all incident dementia cases, 30% of early-onset but only 8% of late-onset cases were due to non-degenerative and non-vascular dementia, with

the commonest causes being cancer, chronic mental illness and alcoholism (Knopman *et al.* 2006). Interestingly, two commonly held views are dispelled by this report: (i) none of the causes of 'reversible dementia' commonly sought, including normal-pressure hydrocephalus, subdural haematoma, hypothyroidism, vitamin B₁₂ deficiency or neurosyphilis, were found and (ii) not a single case of dementia was found to be reversible after treatment. The prevalence of non-degenerative and non-vascular apparent dementia appears to be declining, possibly as a consequence of improved diagnostic practice or possibly because the numbers of people with uncomplicated dementia coming to the attention of specialists is increasing. A review in 1988 of nearly 3000 subjects with dementia found 13% to have a potentially reversible dementia and a follow-up meta-analysis to 2002 including over 5500 patients with dementia showed only 9% to have a potentially reversible dementia and only 0.6% to actually reverse (Clarfield 1988, 2003). These results may not hold true everywhere: in one report from India, a relatively high proportion of neuroinfections and vitamin B₁₂ deficiency was found and in many cases the dementia was indeed reversible (Srikanth & Nagaraja 2005).

A broad attitude to the question of differential diagnosis must be maintained throughout all stages of the clinical enquiry. The history provides important clues, similarly the physical and mental state examinations. Psychometric assessment can be very helpful, especially in borderline cases and in confirming or refuting the global nature of the patient's intellectual difficulties. Certain ancillary investigations will always be needed, as set out below. In the majority of cases the definitive diagnosis will soon become apparent, but occasionally the picture will be perplexing and the search may need to be far ranging. Occasionally, complete investigation will leave one with probabilities rather than certainties, and it will then be necessary to see what course the disorder takes with time. Lack of clear confirmation of the diagnosis will mean that it is essential to keep the patient under regular review, with readiness to investigate anew if later developments are in any way unusual.

History

Family history can be of prime importance in early-onset cases and when the presentation is atypical. Differential diagnosis of a familial dementia includes AD, FTDs, Huntington's disease or familial spongiform encephalopathies. A marked family history of affective disorder may occasionally help towards the identification of depressive pseudodementia.

Antecedent history may contain clues of great significance. Even slight head injury can lead to a subdural haematoma, especially in elderly, arteriosclerotic or alcoholic subjects. This may declare itself only after a considerable latent interval. Normal-pressure hydrocephalus may likewise be

traceable to prior head injury, subarachnoid haemorrhage or meningitis.

Recent fits, faints or episodes of collapse will indicate the possibility of a cerebral tumour, cerebral infarction, episodic hypoglycaemia or an undiagnosed myocardial infarction that has led to cerebral anoxia. Previous episodes of transient neurological disturbance will raise the question of vascular dementia or multiple sclerosis.

Special care must be taken whenever there is a previous history of anaemia, heart disease or chronic pulmonary disorder which may now be leading to cerebral anoxia. The recent administration of an anaesthetic may be significant, or any episode of carbon monoxide poisoning or prolonged coma due to drug overdosage.

Recent illnesses must be viewed in relation to their effects on cerebral function, in particular hepatic or renal disease which may have led to metabolic disturbance, or infective processes that may have resulted in a cerebral abscess.

Dietary neglect may have produced vitamin B or folic acid deficiency, either as a primary aetiological factor or as a complication of the dementing process. A history of gastrectomy may be especially significant in relation to vitamin B₁₂ deficiency. Some patients with dementia and vitamin B₁₂ deficiency do improve after correction of the deficit and those that do may have a somewhat different neuropsychological presentation (Osimani *et al.* 2005).

Alcoholism deserves careful and sometimes pressing enquiry. The progressive inefficiency and deterioration of habits in alcoholic subjects can present as a possible dementing process, and Korsakoff's syndrome can at first sight be mistaken for global intellectual impairment. Drug abuse should be suspected when the picture fluctuates from time to time or when there is a history of similar episodes in the past. A history of relevant behaviours will bring the possibility of HIV infection to mind. Medication recently prescribed should also always be determined. In obscure cases the patient's occupation warrants consideration, with enquiry about the possibility of chronic poisoning from lead, manganese or other chemicals.

Certain symptoms are of importance. Headache, visual disturbance or vomiting will raise the possibility of a space-occupying lesion. Epileptic fits, especially with focal onset, must similarly be noted with care. Other complaints that may indicate focal rather than diffuse cerebral disease include special difficulty with language, trouble in recognising people or objects, or inability to carry out habitual acts and manipulations.

Benson and Cummings (1982) have drawn attention to the 'angular gyrus syndrome' which may easily be confused with AD on account of the number of features they have in common. Such patients present with posterior aphasia, alexia with agraphia, Gerstmann's syndrome and constructional deficits, usually as a consequence of cerebral inf-

arction. The abrupt onset, if known, will give the clue, likewise the preservation of memory and topographical orientation. Malaise, loss of energy and anorexia will suggest anaemia, uraemia or occult malignant disease. A cough of recent onset and severe loss of weight will suggest carcinoma of the lung, which can sometimes present with dementia in the absence of secondary cerebral deposits. Sensitivity to cold will immediately raise the possibility of myxoedema, and excessive thirst or bone pain may suggest parathyroid disorder.

Mode of evolution of the illness is of great diagnostic importance. Separate note must be taken of the nature of the principal early difficulties, the duration up to the time of presentation, the certainty or uncertainty of onset, and the steadiness or otherwise of progression.

Onset with memory disturbance is characteristic of most primary dementias, especially AD, which is the commonest form. In the elderly this may for a time be difficult to distinguish from the 'normal' memory difficulties of old age; the dysmnnesia of senescence typically progresses very slowly, and occurs in a setting of relative preservation of other cognitive processes, whereas in dementia other aspects of intellect usually soon come to be implicated. Any onset with symptoms other than memory disturbance should always raise suspicion. Marked affective disturbance or change of personality may be seen with Pick's disease, other frontal dementias or Huntington's disease, but may equally be indicative of a frontal lobe tumour or general paresis.

A short duration immediately raises the possibility of a secondary dementia due to cerebral tumour, covert cerebral infarction, AIDS or some extracranial cause. In most primary dementing illnesses the symptoms are of long duration, usually of many months by the time the patient presents for attention.

Caution should be paid when interpreting apparently sudden onset as the suddenness may simply represent infrequency of contact between the patient and the informant, especially in the elderly. Anecdotally, onset is not infrequently at national holidays, Christmas and Easter for example, when the elderly person with an early but as yet unrecognised dementia may have more contact with family members, may have more cognitive and functional tasks to perform (e.g. cooking, shopping) and may find themselves in an unfamiliar environment (staying with a relative, being taken on holiday). All these may 'reveal' the dementia, which may then present to the clinician as sudden onset.

A definite date for the onset is also rarely obtained in the primary dementias, which tend to begin so insidiously that neither the patient nor family can give a precise timing to the earliest manifestations. In contrast, with cerebral tumours there is usually some episode or symptom that can later be recalled as the first indication of the illness. This information can be important in tumours that are unaccompanied by headache or other evidence of raised intracranial pressure, or for example in frontal meningiomas which can present with global dementia and lack all focal signs.

Steady progression without remission is typical of all the primary dementias with the exception of multi-infarct dementia. Marked fluctuations from time to time must therefore immediately suggest that one may be dealing not with a chronic but an acute organic reaction, or at least with an acute component superimposed on the basic dementing process. Considerable difficulty can sometimes be encountered in differentiating between a subacute organic reaction and dementia, especially multi-infarct dementia. The elderly are unusually vulnerable to the effects of anoxia or metabolic derangements, and the responsible somatic disease may not be very obvious. A markedly intermittent course, with periods of possible clouding of consciousness or delirium, should therefore be noted with care, and will indicate the need for survey of the cardiac, pulmonary, renal, hepatic and endocrine systems. Fluctuations and periods of remission will also raise the possibility of a subdural haematoma or drug abuse. An intermittent course with discrete episodes of abnormal behaviour may suggest hypoglycaemia, and when severe this can leave enduring dementia in its wake.

Examination

Physical examination is important in suggesting remediable causes of dementia but more so in revealing systemic disorders that may be aggravating the situation, especially in the elderly. The general appearance may suggest myxoedema or malnutrition. Inspection of the skin and tongue may indicate dehydration, vitamin depletion or anaemia. A patient who looks unwell will be suspected of metabolic disorder, malignant disease or some infective process. Common foci of infection in the elderly include low-grade pneumonia or bronchitis, and in women cystitis. A low-grade intermittent pyrexia may raise the possibility of subacute encephalitis, cerebral abscess, collagen vascular disorder or, on rare occasions, multiple embolisation in association with subacute bacterial endocarditis. The cardiovascular state always requires appraisal with regard to hypertension, arteriosclerosis, congestive cardiac failure and the patency of the carotid arteries in the neck.

Neurological examination will rarely reveal marked localising signs in the primary dementias, with the exception of some cases of vascular and poststroke dementia and the rare cases of CJD. Evidence of focal paresis or sensory loss in association with a slowly progressive dementia therefore immediately raises the possibility of a space-occupying lesion. Considerable care must sometimes be taken to exclude visual field defects or unilateral anosmia, which can be difficult in patients who are less than fully cooperative.

Examination of the optic fundi may reveal evidence of raised intracranial pressure. The pupil reactions may betray general paresis, and nystagmus will suggest barbiturate intoxication. A Kayser–Fleischer ring at the corneal margins

will indicate Wilson's disease. Pronounced ataxia in association with memory disturbance will suggest the residue of Wernicke's encephalopathy, and peripheral neuropathy will raise the possibility of alcoholism or heavy metal poisoning. Evidence of dysarthria, minor dysphagia or a brisk jaw jerk may indicate early pseudobulbar palsy, and should be carefully assessed when cerebral arteriosclerosis is suspected.

Early incontinence and unsteadiness of gait are important pointers towards normal-pressure hydrocephalus. Close observation may sometimes be required for the detection of the early choreiform movements of Huntington's disease, and myoclonic jerking in association with dementia will raise the possibility of CJD. Evidence of Parkinson's disease or multiple sclerosis must not be overlooked. The prominent development of parkinsonian features, either early or late in the course, will suggest DLB. Rigidity, tremor or dystonia in the younger patient will raise suspicion of Wilson's disease.

Mental state evaluation is principally directed at establishing the global nature of the intellectual disorder. Care must be taken to avoid mistaking dysphasia, circumscribed amnesic difficulties or parietal lobe symptomatology for global dementia. Somnolence, in the absence of uraemia or other metabolic disorder, will suggest hypothalamic damage. A marked degree of emotional lability with pathological laughing and crying will suggest a vascular process, with an accent on the basal regions of the brain. Any suspicion of clouding of consciousness will immediately raise the possibility that one is dealing with an acute organic reaction rather than dementia, or that there is some complicating toxic, infective or metabolic disorder present.

The mental state evaluation is equally important for the detection of depression presenting as dementia (i.e. pseudodementia). Inconsistencies in the patient's performance may raise the question of a Ganser state, hysterical pseudodementia or even, on rare occasions, simulation. The patient's attitude to his symptoms and the degree to which his purported disabilities interfere with daily life can be observations of crucial importance. Affective changes sometimes need to be sought with care. A marked depressive component may indicate depressive pseudodementia, or concurrent depression may be aggravating the situation in a patient with organic cerebral disease.

Assessment of non-cognitive symptoms in established dementia is critical and should be an ongoing task. These include behavioural change, depression, anxiety, psychosis and personality changes and may be achieved in the clinical context by interview of the informant, assessment of the patient and in many cases with the addition of one of the many excellent scales used widely in research.

Psychometric testing will often be of value. Bedside cognitive testing will be performed in all instances and will include assessment of multiple domains of cognition; it has become

routine to incorporate a standard assessment measure such as the MMSE as a measure of severity, although it should be remembered that this scale was developed as a screening scale. Tests of frontal and parietal function help in the differential diagnosis. Further detailed psychometry, usually by a psychologist, is often helpful but rarely mandatory. It may help in the distinction between organic and non-organic psychiatric illness and with the question of diffuse versus focal cerebral disorder. In very early cases psychometry provides a measured baseline against which future progress can be assessed.

Assessment of function is critical to the full evaluation of the patient. A wide variety of scales are available for research but in clinical practice a very careful history from the patient and the informant is usually sufficient. It can be difficult to assess loss of function in the very early stages and careful and patient assessment of complex tasks that might be expected of the patient and were once easily accomplished is necessary. The assessment of an occupational therapist is often essential to both aid diagnosis and help plan management.

Diogenes' syndrome, squalor and self-neglect (Cooney & Hamid 1995)

Patients are occasionally found to be living in a state of extreme squalor and gross physical neglect, yet prove to be free from any psychiatric disorder sufficient to account for it. In particular, their cognitive functions may emerge as relatively or completely intact. This has been designated Diogenes' syndrome or 'senile self-neglect', although the nosological status of the condition remains uncertain (Pavlou & Lachs 2006). Some may be in the early stages of a dementing illness while others appear to be suffering essentially from personality disorder. Quite often such patients prove to be solitary and reclusive individuals who are reacting to stress, bereavement or loneliness. Hoarding rituals may have become entrenched, and serious medical illness or disability is not uncommon. Orrell *et al.* (1989) have reported marked frontal lobe dysfunction on neuropsychological examination in some instances, raising the possibility that frontal lobe dementia may occasionally be responsible. Reports of such patients underline the need for careful assessment of elderly patients even when first appearances are strongly suggestive of advanced AD. A cross-sectional survey showed 70% of people with self-neglect had a mental health problem, although only half of those had had any contact with mental health services (Halliday 2000).

Investigations

In the primary dementias there are no specific abnormalities in the blood, urine, CSF or neuroimaging. However, there are some indicators that help in differential diagnosis and some promising developments in biomarker research. For the most part investigations are directed at detecting remediable conditions or uncovering systemic disorders that may be worsening the clinical picture.

It is widely accepted that a minimum investigation screen for every patient with dementia includes full blood count, blood urea, serum electrolytes and liver function tests. Tests of thyroid function and vitamin B₁₂ and folate, and in some patients syphilis serology, are appropriate. If delirium is suspected, urine examination should be supplemented by microscopy and where necessary culture. Chest radiography may be performed for the evaluation of cardiac and pulmonary status and as a screen for primary or secondary carcinoma.

Electroencephalography is oft-neglected but can be useful. Non-specific changes occur early in AD and yet the EEG remains entirely normal relatively late in FTD. Specific changes are seen in CJD. The ECG is an important investigation if the patient is being considered for acetylcholinesterase therapy.

Neuroimaging of some sort is considered mandatory by most European and American specialist groups (Beck *et al.* 2000; Knopman *et al.* 2001; Frisoni *et al.* 2003; Kantarci & Jack 2003; Waldemar *et al.* 2007). CT can be used to identify vascular lesions and treatable masses but MRI adds greatly to specificity. Special indications for scanning will include any remote suspicion of a cerebral tumour or subdural haematoma, the presence of focal neurological signs, a history suggestive of cerebral infarction or head injury, or clinical pointers towards normal-pressure hydrocephalus. Imaging shows cerebral atrophy with ventricular dilatation and prominence of cortical sulci but without distortion or displacement of the ventricular system. The distribution of atrophy may point towards a diagnosis of Pick's disease or other frontal dementia, or marked shrinkage of the heads of the caudate nuclei may indicate Huntington's disease. Evidence of old and recent cerebral infarctions may suggest a vascular basis for the dementia. However, these changes are neither sensitive nor specific markers of dementia and questions have been raised regarding its utility in assessment. SPECT and even PET can be used to identify a characteristic pattern of regional brain hypometabolism. Posterior parietotemporal deficits in regional blood flow or metabolism, though not pathognomonic, may add to a suspicion of Alzheimer's dementia while sharply circumscribed frontal deficits may indicate FTD for example.

A raft of neuroimaging techniques are being developed that might be of use in diagnosing or monitoring progression in AD. These include the use of diffusion tensor imaging, functional MRI or PET-based molecular markers of amyloid (Jagust 2004; Masdeu *et al.* 2005; Walker & Walker 2005; Catani 2006). None of these techniques have yet escaped the research context into the clinic but do show promise in doing so.

Lumbar puncture is rarely of value in the routine assessment of people with dementia and is not recommended in typical cases (Waldemar *et al.* 2007). However, it may be

undertaken if the cause for the dementia remains uncertain and when there is no reason to suspect a cerebral tumour or raised intracranial pressure. Examination of the CSF can be decisive in the diagnosis of general paresis in cases when blood serology has been negative. Dementia can also occur with syphilitic arteritis which has produced scattered cerebral infarcts. The first indication of a subdural haematoma may come from an elevated CSF pressure, increased protein or xanthochromia. Subacute and chronic forms of encephalitis may likewise be detected only after examination of the fluid. The assessment of 14-3-3 protein may be useful as it has good sensitivity and specificity for CJD. Biomarkers in CSF are being actively sought and the most promising of these are tau and amyloid (Fagan *et al.* 2005; Sunderland *et al.* 2005). Whether these tests will become part of recommended clinical practice remains to be seen.

Very occasionally it will be deemed advisable to exclude other rare conditions that can give rise to dementia. Wilson's disease is detected by the estimation of serum caeruloplasmin and confirmed by liver biopsy. Neuroacanthocytosis requires examination of fresh blood films and metachromatic leucodystrophy the estimation of arylsulphatase-A in the blood or urine, or biopsies of the peripheral nerve or rectal wall. Kufs disease is detectable by skeletal muscle or rectal biopsy, Whipple's disease by lymph node or jejunal biopsy, and mitochondrial myopathies by a search for 'ragged red fibres' in skeletal muscle biopsy. A search for sarcoid may involve radiography of the phalanges, biopsy of the lymph nodes or skin lesions, and the Kveim intradermal test. Most familial dementias can be categorised by genetic testing, although it is important to bear in mind that this is not a diagnostic test as the mutation will have been present for life. Even in these cases where an absolute molecular categorisation can be made, the diagnosis of whether the patient is affected relies on the clinician's skill and sensitivity in establishing the very early symptoms.

Management of dementia

The reader would be well advised to consult recent guidelines on management of dementia for current treatment strategies, especially when it comes to pharmacotherapy of both the dementia and the behavioural symptoms in dementia. Here the general principles of management are discussed. The first step in management is always full medical evaluation along the lines already discussed. This is necessary for firm establishment of the diagnosis, the exclusion of remediable conditions masquerading as primary dementia, and to check on any concurrent disease that may be aggravating the symptoms. In cases where the first evaluation has given equivocal results, this must be borne in mind during follow-up, with readiness to reopen investigations if the course is in any way unusual.

Diagnosis and information

After establishing the diagnosis, both the disease and the person suffering from it together with their carers and wider family must be kept in mind. Difficult decisions will often have to be made over such questions as continuation with work in early-onset cases and how fully to explain about prognosis. The clinician will need to consider, with the patient and his or her family, whether the patient should continue to drive and later perhaps whether to continue to live at home. On all these issues much will depend on factors specific to the individual and his family.

Attitudes to sharing the diagnosis with the patient are changing and now almost all patients with mild dementia wish to be told (Pinner & Bouman 2003). Family members may be less sure and indeed may request the clinician not to disclose the diagnosis, placing him or her in a difficult situation (Hughes *et al.* 2002). Disclosing diagnosis and discussing prognosis is a sensitive task and needs to be approached with skill and with care. Reassurance is not, in the end, reassuring when inappropriate and yet it is true that an unnecessarily pessimistic attitude concentrating on only negative consequences and a hopeless outlook is not helpful to either the patient or the carer. General counselling principles apply here as much as elsewhere in medicine and the most thoughtful clinicians will convey an attitude of care and attention, will share the facts and information they have, will have time to address fears and concerns and will above all be guided and led by the recipient of the information, be that the patient or the family.

Many families and patients benefit from contact with a carer or lay organisation. There are many such including the Alzheimer's Society in the UK and the Alzheimer's Association in the USA. An umbrella body, Alzheimer's Disease International, encourages the growth of similar societies throughout the world. These groups provide a wealth of information through local groups, through their websites and with pamphlets, books and leaflets. No carer should remain ignorant of their existence. Carer groups are immensely valuable for many families and may be organised by clinical services or the lay societies.

One issue that should be addressed as early as possible concerns the long-term financial and legal standing of the patient. In the UK the establishment of a lasting power of attorney, whereby the patient's financial affairs are placed in the hands of another, is the main mechanism for this. There are similar arrangements in many other countries. Most countries, including the UK, have separate legal frameworks for establishing decision-making on behalf of a person already rendered incapable of making complex decisions and for setting out advance directives for future health care and for passing over decision-making to a responsible other

person before capacity is lost. Clearly, where possible, the latter is preferable.

Community and residential care

The vast majority of people with dementia remain at home for an extensive period and many remain at home throughout their illness. A comprehensive service for people with dementia will integrate medical and other clinical care providers with social care providers. A case or key worker can help to integrate these elements with services provided by the voluntary sector. The care of a person with dementia is complex and changes as the illness progresses. The patient's needs will differ over time and the family will have needs as well that should be considered.

In the early stages all that may be required is information and possibly the support of a care worker or a support group. As the patient becomes more impaired then home care might include the provision of meals, cleaning services, shopping, supervision or other services. Carers can be provided with support and respite. A day unit, usually a day-centre, sometimes a day-hospital, might be needed to provide respite and also more detailed ongoing assessment and activities. In some services home care can be provided multiple times a day, seven days a week; in other areas such requirements point to the need for residential care.

When the patient can no longer be managed at home, optimal placement must be arranged. Much will depend on local facilities and the extent to which social, psychiatric and geriatric services have become organised. Families may resist residential care at first, feeling guilty or considering this a slight on their provision of care. Sensitive handling is needed. Care does not stop at the door of a residential home and the best homes are well supported by local service providers. Preparation should ideally be made well in advance of the time when this is likely to be required, although this is not always possible. The needs of different patients are widely variable, and should ideally be matched by a similarly broad range of resources.

The stress experienced by families caring for a demented relative, sometimes called burden, has been extensively studied (Burns 2000). Up to one-quarter of all carers experience significant stress or anxiety and the rates of carer burden are higher when caring for a patient with more severe behavioural symptoms (Sorensen *et al.* 2006), although there are other determinants of carer stress including younger carers, financial difficulties and perceived stigma (Freyne *et al.* 1999; Schneider *et al.* 1999; Cooper *et al.* 2007).

The range of therapies for people with dementia is wide, although the evidence base for many is variable (Bates *et al.* 2004; Robinson *et al.* 2006). The reader is directed towards recent studies of validation therapy (Neal & Briggs 2003; Tondi *et al.* 2007), reality orientation therapy (Onder *et al.* 2005), cognitive stimulation therapy (Spector *et al.* 2003) and

aromatherapy (Ballard *et al.* 2002b; Thorgrimsen *et al.* 2003) for example. While awaiting a more complete evidence base the pragmatic clinician combines the possible with the appreciated and hopes for the best.

Medical management

The medical management of dementia is undergoing rapid developments, with the availability of new drugs for both the disease itself and treatment of behavioural symptoms. Optimal physical health must be maintained if the patient's deterioration is to be slowed and the best use made of residual functions at any given stage. Attention to adequate nutrition, hydration and vitamin replacement can sometimes meet with gratifying improvement. The elimination of infection is a matter for repeated checks, particularly chronic infection within the lungs or urinary tract. Any tendency towards congestive cardiac failure, cardiac dysrhythmia or anaemia must be treated energetically. Hypertension, when severe, will warrant appropriate management. Special care must be taken to guard against iatrogenic disorders, particularly electrolyte imbalance due to diuretics and toxicity from other drugs. A recent study showed a very substantial effect of drugs on rates of progression, with some prescribed drugs accelerating and some slowing progression (Ellul *et al.* 2007).

In vascular dementia there will often be a special case for strict control of hypertension, and sometimes for treatment with anticoagulants or aspirin. However, management decisions should be made on the basis of cardiac disease because there is insufficient evidence to currently recommend any treatment for the dementia itself (Waldemar *et al.* 2007). Other vascular risk factors such as hypercholesterolaemia or diabetes will need special attention. Vasculitis may require treatment with corticosteroids.

Adequate physical exercise must be encouraged, sometimes with the aid of physiotherapy. Orthopaedic complications may need attention in the elderly. Adequate daily activity will induce normal fatigue and lessen the incidence of disturbed and restless nights. It will also help defer the time when nursing in bed, and hence the terminal stages, are reached. There is some evidence that exercise may even delay decline (Rolland *et al.* 2007).

Psychotropic medication will often be needed to allay agitation and depression. In general, however, one will wish to avoid using drugs with strong anticholinergic effects for prolonged periods, in view of the known cholinergic deficits in AD. Treatment of depression should be vigorous and pharmacotherapy should avoid antidepressants with significant anticholinergic action; arguably this makes one of the best cases for using a selective serotonin reuptake inhibitor (SSRI). Disappointingly, few trials have been conducted but those that have show a beneficial effect of SSRIs (Lyketsos *et al.* 2003; Rao *et al.* 2006). Pharmacology

therapy must be combined with non-pharmacological management.

Treatment of other BPSD also requires a combined pharmacological and non-pharmacological approach, with the emphasis on the latter not only because it is most efficacious but because it is safest (Ayalon *et al.* 2006; Angelini *et al.* 2007; Bird *et al.* 2007). Pharmacological treatment of BPSD is difficult and the general approach of 'start low, go slow' should be adopted. Atypical antipsychotics have been most studied and a meta-analysis finds some evidence of efficacy in BPSD (Schneider *et al.* 2006a). However, antipsychotic medication is most efficacious for psychosis and rarely has any effects on generalised behavioural disturbance other than general sedation. The evidence that atypical antipsychotics have an increased rate of serious adverse effects and indeed increased mortality in this group of patients is growing and these drugs should be used only under very strict scrutiny, by engaged clinicians reviewing the need for the medication regularly and only in extremis when all other approaches have failed. It may be that the lack of evidence for adverse effects of typical antipsychotics simply represents absence of evidence rather than evidence of safety. In general, the results from one large multicentre trial match the views of many clinicians who have come to the conclusion that for many patients the benefits of antipsychotics in dementia is outweighed by their side effects (Schneider *et al.* 2006b).

Alzheimer's disease

In the late 1990s the first specific drugs for AD received a licence. The acetylcholinesterase inhibitors, currently donepezil, rivastigmine and galanthamine, have been shown to be efficacious and safe in AD (Francis *et al.* 1999; Birks 2006; Burnes *et al.* 2006). Their use is widely recommended, although reimbursement and support for their prescription is variable, not least as there is little evidence that they are cost-effective. In the UK an extensive set of reviews by the National Institute for Clinical Excellence (NICE) has currently concluded that they should be prescribed for patients with moderate AD only. A second class of drug, currently represented only by memantine, was shown to be efficacious in severe dementia and is licensed and widely prescribed in the USA and in Europe but is not recommended by NICE (Robinson & Keating 2006; Cosman *et al.* 2007).

In general terms, treatment with cholinesterase inhibitors has followed guidelines established for a decade or so (Lovestone *et al.* 1997). Patients should be monitored throughout: early and frequently for titration and for assessment of side effects and less often but continuously for efficacy. Expectations of patients and carers should be managed: these drugs have a modest effect, at best, and decline continues regardless. When a patient progresses to the point that the drug is unlikely to be having a benefit, then it should be stopped and carers should have been warned that this will occur at the outset. A drug holiday can be useful in establishing whether

the drug is still having an effect, although precipitous falls in cognition can occur and carers should be primed to urgently restart medication.

Other disorders

There is no evidence for a specific indication of any therapeutic approach in a non-AD dementia. However, there is some limited evidence that patients with DLB respond to cholinesterase inhibitors and to levodopa (McKeith *et al.* 2005; Liepelt *et al.* 2007) and excellent evidence that these patients can have a severe and sometimes fatal response to antipsychotic medication. The evidence base for the use of cholinesterase inhibitors in vascular dementia is not as strong as that for AD and the drugs are not licensed for that condition. However, given that most patients with 'vascular dementia' also have changes of AD and vice versa, it is not surprising that many patients respond to cholinesterase inhibitors in much the same way as patients with AD (Erkinjuntti *et al.* 2004). There is little or no evidence that lowering blood pressure is beneficial to the dementia condition (McGuinness *et al.* 2006). Specific treatment may help in Huntington's disease for the control of choreic movements. Phenothiazines are widely employed for this purpose and have been shown to be effective, especially haloperidol. However, a meta-analysis and systematic review failed to make any robust clinically relevant recommendations (Bonelli & Wenning 2006).

Endocrine Diseases and Metabolic Disorders

Neil A. Harrison¹ and Michael D. Kopelman²

¹Institute of Cognitive Neuroscience, University College, London

²Institute of Psychiatry, King's College, London

The relationship between endocrinology and psychiatry continues to attract considerable attention. Endocrine disorders can be accompanied by prominent abnormalities of the mental state, as for example in hypothyroidism and hyperthyroidism, and epochs of life such as after childbirth that are associated with rapid changes in hormonal levels appear to be associated with special liability to mental disturbance. Conversely, it is now clear that primary emotional disorders are accompanied by changes in neuroendocrine regulatory functions and may even predispose to the development of endocrine disorders such as diabetes mellitus.

Historically, treatment by means of hormones has often been viewed as a possibility in psychiatry. Kraepelin (1896) once proposed that dementia praecox was basically an endocrine disorder. Others have speculated on the role of hormones in regulating the 'biological background of psychic life', noting their influence on characteristics such as impulsivity, attention, arousal and motivational drive (Bleuler 1967). More recently, studies of patients treated for hypopituitarism have revealed that hormones such as growth hormone, previously thought to play a role only in childhood and adolescence, continue to be important to mental well-being and metabolic function throughout adult life. On the other hand, exogenous administration of hormones, most notably corticosteroids, may lead to the development of cognitive, psychotic or affective disorder.

Recent research has continued to pursue the question of how hormones influence fundamental aspects of brain development and human behaviour during both early childhood development and later adult life. Experimental work in animals has clarified the morphological basis by which lack of thyroxine during early development impairs the maturation of behaviour (Eayers 1968). Prenatal steroid hormones have a decisive influence in animals on sexual differentiation and on a wide range of sexual and social behaviours (McCarthy 1994; Signoret & Balthazart 1994). Elegant experimental design coupled with functional neuroimaging

technologies are also beginning to provide exciting new insights into the mechanisms through which hormones such as vasopressin and oxytocin influence social recognition and the expression of appropriate social responses in adult life (Kosfeld *et al.* 2005; Storm & Tecott 2005). Findings such as these illustrate the important interactions between endocrine systems and psychological function and in the words of William James 'make us realise more deeply than ever how much our mental life is knit up with our corporeal frame' (James 1890).

This chapter includes sections on Turner's and Klinefelter's syndromes and the metabolic disorders of hypoglycaemia, malnutrition, vitamin B deficiencies, uraemia and electrolyte disturbance. Research into Turner's syndrome continues to illuminate the differential roles of imprinted genes on the X chromosome and hormonal deficiencies on the specific cognitive deficits and difficulties in social functioning seen in girls with the condition. The metabolic disorders illustrate the importance of a stable biochemical and metabolic milieu for the proper functioning of the central nervous system (CNS). They are a group of disorders seen quite frequently in unwell patients admitted to medical or surgical wards and are encountered quite commonly by liaison psychiatrists in general hospitals. Porphyria is included as a rare but striking example of an inborn error of metabolism with important psychiatric features.

The chapter focuses on the clinical psychiatric manifestations of the primary endocrine disorders, discussed together with the results of relevant research literature. Whilst a significant majority of patients with the conditions discussed will present either to a general physician or general practitioner, occasional individuals will present in such a way that psychiatric manifestations dominate the clinical picture and the endocrine disturbance may go unnoticed. With some conditions, for example hypothyroidism and Addison's disease, the psychiatric abnormalities may be so marked that there is a constant risk of mistaken diagnosis.

Diabetes mellitus

Diabetes mellitus is a group of metabolic diseases characterized by hyperglycaemia resulting from defects in insulin production, insulin action or both. Recent consensus opinion has advised a change to an aetiopathologically based classificatory system (Expert Committee on the Diagnosis and Classification of Diabetes Mellitus 2003), with the vast majority of cases fitting into one of two broad categories. In type 1 diabetes the associated abnormalities of protein, carbohydrate and fat metabolism are the result of insufficient insulin action on peripheral target tissues as a result of reduced insulin secretion, whereas in type 2 diabetes these metabolic abnormalities are the result of diminished tissue response to insulin with or without an associated deficiency in insulin secretion. Type 1 diabetes is associated with pancreatic islet β -cell loss that results in proneness to ketosis. Most cases typically present by age 20 and appear to be the result of an autoimmune reaction, possibly triggered by an environmental insult, on a background of raised genetic susceptibility. Type 2 diabetes likely results from a combination of inadequate insulin secretion and peripheral insulin resistance. Insulin levels may be higher than seen in normals but are insufficient to overcome resistance in liver, muscle and adipose tissue. Published prevalences of type 2 diabetes depend on the diagnostic criteria used and the age and racial composition of the population studied, being higher in older populations and in certain ethnic groups such as Pima Indians living in the USA. In the UK, the prevalence of diabetes mellitus is 3–5% (Forrest *et al.* 1986; Yudkin *et al.* 1993), with type 2 diabetes seven to eight times more common than type 1.

It is well established that genetic mechanisms contribute to the development of both forms of the disease, and interesting progress has been made in relation to type 1 diabetes (Bennett *et al.* 1995; Kennedy *et al.* 1995). Multiple loci are clearly involved, including loci on chromosome 6 in the human leucocyte antigen (HLA) region, and on chromosome 11 in close relation to the insulin gene itself. The insulin gene is flanked upstream by multiple repeats of a 14-bp sequence, variations in length of the sequence correlating with disease susceptibility, perhaps through a direct effect on transcription of the insulin gene. Genetic influences in type 2 diabetes are especially apparent in patients who are not overweight, including, it seems, changes in mitochondrial DNA. Textbooks of medicine should be consulted for the general clinical associations of the disorder and the principles of management by diet, insulin and oral hypoglycaemic agents.

Diagnosis of diabetes is of importance to psychiatry for a number of reasons. Psychiatric disorders, particularly emotional disorders, are more prevalent in the diabetic population, whilst the development of depression in diabetic patients is associated with poorer glycaemic control, higher

Table 10.1 Criteria for the diagnosis of diabetes mellitus. (From American Diabetes Association 2004.)

Normoglycaemia

Fasting plasma glucose (FPG) <5.6 mmol/L
2-hour post-load glucose (PG)* <7.8 mmol/L

Impaired fasting glucose or impaired glucose tolerance

Impaired fasting glucose: FPG \geq 5.6 and <7.0 mmol/L
Impaired glucose tolerance: 2-hour PG \geq 7.8 and <11.1 mmol/L

Diabetes†

FPG \geq 7.0 mmol/L
2-hour PG \geq 11.1 mmol/L
Symptoms of diabetes and casual plasma glucose concentration \geq 11.1 mmol/L

* This test requires the use of a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water.

† In the absence of unequivocal hyperglycaemia, a diagnosis of diabetes must be confirmed, on a subsequent day, by measurement of FPG, 2-hour PG or random plasma glucose (if symptoms are present). The FPG test is greatly preferred because of ease of administration, convenience, acceptability to patients and lower cost. Fasting is defined as no caloric intake for at least 8 hours.

prevalence of multiple diabetic complications and greater functional impairment. Furthermore, mood disorder appears to be an independent risk factor for the development of type 2 diabetes. A number of medications commonly used by psychiatrists, including all the antipsychotic drugs, are associated with an increased incidence of diabetes. It is therefore important that all practising psychiatrists should be familiar with current diagnostic criteria for diabetes mellitus, enabling any patient developing diabetes to be rapidly identified and referred for appropriate treatment. Failure to do so will unnecessarily expose patients seen by psychiatrists to increased risk of developing cardiovascular disease and diabetic microvascular complications. Diagnostic criteria are shown in Table 10.1. These issues are discussed below, along with the question of brain damage in diabetic patients. When evidence of brain damage emerges this may be attributable to episodes of hypoglycaemia or diabetic coma or, alternatively, to the high incidence of atherosclerosis that exists in patients with diabetes. The picture of diabetic coma, and certain common neurological complications, are also briefly described.

In several ways the situation imposed by diabetes is unusual in comparison with other chronic diseases. Patients with diabetes are required to comply with strict dietary restrictions and daily self-administered injections. This incurs a responsibility that is rare in other illnesses. Adherence to dietary regimens may be particularly difficult during periods of loneliness, depression or tension, whilst rebellion in adolescents may be associated with wilful neglect of treatment. Pruritis and decreased sexual interest may contribute

to emotional complications, and impotence and amenorrhoea can be early complaints even in undiagnosed diabetics. Physical handicaps resulting from ocular and other complications further increase the burden of the disease. A major fear among many who inject insulin is the occurrence of a hypoglycaemic attack, especially those that lack the adrenergic warning in which loss of self-control or bizarre behaviour may occur. Tighter glycaemic control has led to more frequent hypoglycaemic episodes, which may themselves be associated with chronic long-term disability (Diabetes Control and Complications Trial Group 1997).

Depression as a risk factor for diabetes

Recent longitudinal studies suggest that depression is an important independent risk factor for the development of type 2 diabetes. Individuals with psychiatric illnesses often also have a number of risk factors for the development of diabetes, including physical inactivity and obesity (Hayward 1995). However, even after controlling for potential confounders such as age, race, gender, socioeconomic class, education, health service use, other psychiatric disorders and body weight, depression remains a significant risk factor for the development of diabetes (Musselman *et al.* 2003).

Eaton *et al.* (1996) in a follow-up study of 3481 participants in the Epidemiological Catchment Area study showed that subjects who had experienced an episode of major depressive disorder had a 2.2 times higher risk of developing type 2 diabetes in the following 13 years. Controlling for age, race, sex, socioeconomic status, education, use of health services, other psychiatric disorders and body weight did not weaken the association. In a second large prospective cohort, Kawakami *et al.* (1999) followed 2764 male employees of a Japanese electrical company for 8 years. Participants were screened at study entry for depression using the Zung self-rating depression scale and yearly for development of diabetes. Over the 8-year follow-up 43 subjects developed type 2 diabetes, of whom nine had moderate or severe levels of depression at study onset. After controlling for eleven other risk factors (age, education, occupation, work shift, obesity, leisure-time, physical activity, smoking, alcohol consumption, chronic medical conditions and family history), subjects with moderate to severe levels of depressive symptoms at baseline had a 2.3 times higher risk of type 2 diabetes at follow-up compared with those who were not depressed or had low levels of depressive symptoms at study onset.

Prevalence of depression in diabetic patients

Debate continues to surround the issue of whether depression is more prevalent in patients with diabetes mellitus, particularly with respect to patients with other chronic diseases. Studies using self-report measures tend to produce much higher prevalences than those that determine the

presence of psychiatric comorbidities using structured or semi-structured diagnostic interview (Anderson *et al.* 2001). Many studies were also very small and exposed to selection bias, studies were non-randomised and, in some, subjects had volunteered.

Two meta-analyses have reviewed the literature in this area. Gavard *et al.* (1993) found a mean prevalence of depression in individuals with diabetes of 14% by diagnostic interview and 32% using self-report symptom scales in controlled studies and 15.4% and 19.6% in uncontrolled. The meta-analysis by Anderson *et al.* (2001) included studies of 'clinically relevant' depression in diabetes. Within this definition they included studies of both major and minor (or subsyndromal) depression, both of which have been shown to be associated with increased medical morbidity and mortality even after adjustment for health status and health behaviours. They included 42 studies, 48% of which were controlled. Of the controlled studies, 10 reported depression estimates separately by type of diabetes, giving an odds ratio of 2.9 in both the type 1 and type 2 groups compared with non-diabetic controls. Analysis yielded similar odds ratios for men and women, for community versus clinical groups, and for self-report measures versus clinician assessment. They concluded that although the prevalence of depression varied considerably across trials, the odds ratio comparing diabetic with non-diabetic groups was more consistent, with patients with diabetes twice as likely to be suffering from depression as non-diabetic controls (95% CI 1.8–2.2).

However, a subsequent large cross-sectional community study using a modified version of the Composite International Diagnostic Interview found that people with diabetes were no more likely than the non-diabetic population to have a mental disorder as defined by the Diagnostic and Statistical Manual of Mental Disorders (DSM)-IV (Kruse *et al.* 2003), although a higher prevalence of anxiety disorders was found. The odds ratio for an anxiety disorder was 1.93 (95% CI 1.19–3.14). A higher prevalence of affective disorders was found in the diabetic group, though this did not survive correction for age, sex, marital status and socioeconomic status. A further study comparing patients who had previously been hospitalised with either diabetes or osteoarthritis found no difference in rates of subsequent hospitalisation for moderate or severe depression between these groups (Kessing *et al.* 2003). Due to the specific nature of this group, generalisation to the wider diabetic population is difficult though the authors argue that these results suggest that older patients with diabetes do not have an increased risk of developing severe depression compared to patients with other chronic diseases.

Impact of depression on the course of diabetes

Patients with diabetes may sometimes show a close relationship between distressing life events and periods of poor

diabetic control, which may even lead to the development of ketotic coma.

Increased levels of depressive symptoms are associated with poorer adherence to a diabetic diet, poorer compliance with oral hypoglycaemic medication and greater functional impairment (Ciechanowski 2000) and meta-analyses link depression in diabetes with hyperglycaemia and an increased risk of complications (de Groot *et al.* 2000; Lustman *et al.* 2000). Three randomised controlled trials have shown that treatment with either antidepressant medication or cognitive behavioural therapy that results in improvement in mood is also associated with an improvement in glycaemic control (Lustman *et al.* 1997, 1998, 2000). In patients with pre-existing diabetes, depression is also an independent risk factor for coronary heart disease and appears to accelerate the presentation of coronary heart disease (Forrest *et al.* 2000).

Whether direct metabolic consequences of depression are responsible for the increased prevalence of diabetes in depression and for the increase in diabetic complications, or whether these result from the secondary effects due to poor dietary and medication compliance, remains uncertain. When under stress or depressed some people may overeat and neglect their diet or increase their alcohol consumption. Occasionally, patients may also deliberately neglect their medication to precipitate hospital admission at times of crisis.

Depression is also associated with abnormalities in a number of metabolically significant pathways. Early experimental observations showed that emotionally stressful experiences can produce fluctuations in levels of blood glucose and ketone bodies in both normal people and those with diabetes (Hinkle & Wolf 1952a,b). Psychologically stressful conditions are accompanied by release of hormones that counter the action of insulin (i.e. catecholamines, glucocorticoids, growth hormone and glucagons) and are correlated with higher blood glucose levels in non-diabetics (Wing 1985). Numerous studies have reported that depressive disorders are associated with activation of these counter-regulatory hormones (Musselman *et al.* 2003). The initial acute increase in blood glucose in response to stress is associated with increased activity of the sympathoadrenal and hypothalamic–pituitary–adrenal axis with release of adrenaline (epinephrine) and glucagon. This is followed by the combined actions of growth hormone and glucocorticoids, which prolong the increase in blood glucose over hours (Surwit *et al.* 1992).

Some authors have suggested that chronic depressive symptoms may be conceptualised as a stress response gone awry, with the increased release of counter-regulatory hormones and cortisol, activated sympathetic nervous system activity and/or other endocrine disturbances impairing the body's ability to handle a carbohydrate load (Musselman *et al.* 2003). A further consequence of this increased counter-regulatory hormone release may be the impaired insulin and

glucose tolerances seen in insulin and glucose tolerance tests respectively in patients with major depression.

Whatever the mechanisms, mild and more severe depression may have an important bearing on the course of diabetes, leading to worsening of diabetic control and increased diabetic complications. Effective treatment facilitates adherence to diet and exercise and results in improved glycaemic control.

Brain damage in diabetes

Diabetes is associated with both microvascular and macrovascular disease and in type 1 diabetes the risk of additional exposure to intermittent severe hypoglycaemia, all of which may play a part in the development of brain damage in patients with diabetes. Prospective epidemiological studies have shown that diabetes is associated with a greater than twofold increase in the risk of deterioration in cognitive function test scores over 4 years of follow-up (Fontbonne *et al.* 2001). In women the risk of cognitive decline was greatest in those with diabetes of the longest duration (Knopman *et al.* 2001). Stroke is more frequent in diabetes and the risk of vascular dementia is increased 1.5–2.8 fold (Strachan *et al.* 2003). Conflicting data exist on the association of type 2 diabetes and Alzheimer's disease, with some authors arguing for a direct relation and others suggesting that any increased incidence is due to an increase in misclassified cerebrovascular disease. To date studies have lacked sufficiently detailed clinical assessments to allow the differential contribution of macrovascular disease, hypertension, chronic hyperglycaemia, hyperinsulinaemia and other factors to be determined and future detailed prospective studies are required to determine the relative contributions of each of these mechanisms.

Severe protracted hypoglycaemia associated with type 1 diabetes is rare but may lead to permanent neurological and cognitive deficits. Occasional reports have also described localised neuroimaging changes predominantly affecting the frontal lobes and deep grey matter, which appear more susceptible to hypoglycaemia-induced damage (Auer & Siesjo 1993). Acute hypoglycaemia is associated with symptoms of neuroglycopenia (see Acute and subacute neuroglycopenia, later) and may, if left uncorrected, proceed to coma. Cognitive function following acute mild hypoglycaemic episodes recovers within an hour though mood disturbances may take longer to recover (Strachan *et al.* 2000). In more severe hypoglycaemic episodes cognitive function has usually recovered within a day and a half, although mood disturbance and energy levels may be recovered more slowly (Strachan *et al.* 2000). The role of recurrent severe hypoglycaemic episodes in inducing persistent cognitive impairment and brain damage has been the subject of many recent trials, perhaps triggered by the recognition that subjects on intensive insulin therapy are at a threefold higher risk of

severe hypoglycaemic episodes (Diabetes Control and Complications Trial Research Group 1997).

An early study (Bale 1973) that compared individuals with diabetes for 15 years or more with age- and sex-matched controls showed an association between diabetes and impaired scores on a test of new learning and suggested an association between low scores and apparent severity of past hypoglycaemic episodes. However, subsequent prospective studies have reported no association between the frequency of previous severe hypoglycaemic attacks and long-term cognitive impairment (Diabetes Control and Complications Trial Research Group 1996; Reichard *et al.* 1996; Austin & Deary 1999). Austin & Deary (1999) re-analysed the data from the Diabetes Control and Complications Trial and found that repeated episodes of hypoglycaemia were not associated with a decline in spatial ability, processing speed, memory or verbal ability. Ferguson *et al.* (2003) assessed whether a history of previous hypoglycaemia and the presence of background retinopathy was related to cognitive function and brain structure in 74 young people with type 1 diabetes. Severe hypoglycaemia did not influence cognitive ability or brain structure, whilst diabetic retinopathy was associated with small focal lesions in the basal ganglia and worse scores in terms of performance IQ, verbal fluency, and attention and concentration. Taken together these results suggest that at least in younger people with diabetes, episodes of hypoglycaemia are not generally associated with significant long-term cognitive impairment.

However, cross-sectional and case-control studies of older adults with a longer duration of disease have demonstrated a modest but significant decrement in cognitive function associated with the frequency of preceding severe hypoglycaemia. Wredling *et al.* (1990) compared 17 patients with insulin-dependent diabetes and histories of recurrent severe hypoglycaemic episodes with 17 diabetic patients without. The groups were matched for sex, age, duration of diabetes, injection frequency, dose of insulin and socioeconomic factors. On neuropsychological assessment, the group who had experienced hypoglycaemic episodes performed significantly less well on tests of finger tapping, digit span, Necker cube reversals and maze learning. Langan *et al.* (1991) tested 100 insulin-dependent patients on an extensive psychometric battery, after excluding those who had evidence of other causes of brain damage including cerebrovascular disease. Using a questionnaire to assess the number, frequency and severity of previous hypoglycaemic episodes, the authors found significant correlations between the frequency of severe hypoglycaemia and an index of intellectual decline (discrepancy between NART and WAIS IQ), all of the WAIS performance subtests and a forced choice reaction time test. Speed of information processing as measured by the Paced Auditory Serial Addition Task correlated with the estimated number of hypoglycaemic episodes sustained during the patient's lifetime.

A patient reported by Mace (1987) raised the possibility of memory impairment secondary to self-induced hypoglycaemias. A 29-year-old computer manager had abused many drugs and had drunk excessively from his teens; diabetes was diagnosed at 25. He developed severe hypoglycaemic episodes, some with convulsions and automatisms and prolonged bouts of disinhibited behaviour. In hospital it was noted that such episodes were frequent when he was left to measure and administer his own insulin, but stopped when it was given under nursing supervision. He denied deliberate abuse of insulin, but phials and syringes were found concealed among his possessions along with other drugs. His memory was clearly faulty for events of the previous year, and testing confirmed the presence of severe verbal memory deficits. It was difficult to know how far the insulin hypoglycaemias had contributed to this rather than the abuse of alcohol and other drugs.

Diabetic coma

In addition to the complications discussed above, patients with diabetes are susceptible to two metabolic emergencies: diabetic ketoacidosis and hyperosmolar non-ketotic coma. Diabetic ketoacidosis is a complication of type 1 diabetes and usually occurs on cessation of insulin or in the face of markedly increased requirements, such as during infection or at times of increased emotional stress; very occasionally, patients may present in this way without being known diabetics. Hyperosmolar non-ketotic coma usually occurs in type 2 diabetes.

Prodromal symptoms of diabetic ketoacidosis consist of weakness, thirst, dull headache, abdominal pain, nausea, vomiting and drowsiness. The onset may be abrupt or insidious. It is sometimes very gradual over several hours, so that a patient with a dangerous ketosis may still be fully ambulant. Air hunger and heavy laboured breathing develop. The patient becomes increasingly listless and in about 10% becomes comatose, sometimes after a period of restlessness, irritability and confusion. The pulse is weak and rapid and the blood pressure low. Dehydration is marked, the face flushed, and acetone may be smelled on the breath. Investigations will reveal large amounts of glucose and ketones in the urine, and blood glucose with ketosis. Acidosis is marked and the blood urea may be raised. Cerebral oedema and disseminated intravascular coagulation are serious complications. On initial examination the picture may be hard to distinguish from hypoglycaemic coma or from advanced renal failure. Overdosage with salicylates can also give a closely similar picture. In older subjects the differential diagnosis must sometimes include a cerebrovascular accident, since glycosuria may also occur in such a situation.

Hyperosmolar non-ketotic coma is a condition of profound dehydration. There is no associated ketoacidosis, but

serum osmolality and glucose are both extremely high. It typically occurs in elderly patients who become hyperglycaemic due to an infection or other complication; they are unable to drink sufficiently to make up for urinary losses resulting from a hyperglycaemic diuresis. Onset may be gradual, sometimes developing over several days or weeks. The presenting picture may be of gradually increasing lethargy and impairment of consciousness but, unlike ketotic coma, seizures and focal neurological signs are common. The patient may at first be thought to be suffering from an acute stroke, presenting with hemiparesis, aphasia or simple or complex hallucinations (Guisado & Arieff 1975). The condition is usually reversible with correction of the metabolic abnormalities. Autonomic changes can include hyperpnoea and hypertension.

Neurological complications

Neurological complications of diabetes are common. Peripheral neuropathy may affect 10–50% of diabetic patients (Chaudhuri 1997) and can be a severe and distressing complication. Newly diagnosed patients sometimes complain of pain, paraesthesiae and restlessness of limbs, usually distally, symptoms that generally resolve with treatment of the hyperglycaemia. Other reversible neuropathies may be due to individual nerve or nerve root damage or due to cranial neuropathies. Diabetic amyotrophy (femoral neuropathy) is an unpleasant and often extremely painful condition that frequently develops over several weeks and is associated with wasting in one or both anterior thigh muscles. Most patients recover completely but may require strong analgesia for many months. Acute or subacute cranial nerve lesions, usually affecting cranial nerves III or VI or more rarely IV or VII, may also occur. If the third cranial nerve is affected, the pupil is usually spared. Recovery is usually complete within 6–8 weeks. In the elderly irreversible pupillary changes include meiosis, irregular pupils with sluggish light reflex, and sometimes the classic Argyll Robertson pupil (pseudotabes).

A symmetrical somatic polyneuropathy often develops over many years and is related to the duration of diabetes and other microvascular complications. Unfortunately no treatment has been shown to satisfactorily treat this. A painful neuropathy may occur in association. These may present with painful feet, the pain often being severe and unremitting with a burning type sensation and frequently accompanied by allodynia and hyperpathia. Patients may also complain of restless legs or of a sensation of swollen feet. Autonomic dysfunction, usually of the parasympathetic nervous system with preserved sympathetic function, is also common. Impotence is the commonest symptom, and sildenafil and related agents are now widely prescribed in diabetic clinics. Other symptoms such as postural hypotension, gustatory sweating and gastrointestinal complications may

occur. Diabetes is also a risk factor for carotid or vertebral basilar circulation territory strokes and transient ischaemic attacks and is associated with a relative risk of 1.5–3 (Marshall 1993).

Hypoglycaemic disorders including insulinomas

Spontaneous hypoglycaemia is associated with a number of diseases but is seen most frequently clinically following overjudicious use of insulin in diabetes mellitus. Its importance in psychiatry lies in the range of predominantly cerebral symptoms associated with hypoglycaemic disorders and because accurate identification of hypoglycaemic episodes, which may mimic many psychiatric conditions, may lead to diagnosis of the underlying disorder and curative treatment.

The definition of hypoglycaemia is broadly accepted as a blood glucose concentration below 3 mmol/L (Marks & Teale 2001). There is considerable interindividual variability in both the symptoms experienced during hypoglycaemic episodes (Hepburn *et al.* 1991) and the blood glucose levels at which they occur. In experimentally induced hypoglycaemia, symptoms are not usually present until the arterial blood glucose falls below 3.5 mmol/L, equivalent to a venous blood glucose level of 3.3 mmol/L, just below the level at which homeostatic mechanisms opposing the action of insulin become active. The symptoms are caused by neuroglycopenia, literally a shortage of glucose in neurones, and have been classified into three distinct syndromes (Marks & Teale 2001; Marks 1981a).

Acute and subacute neuroglycopenia

This is the commonest picture associated with experimental hypoglycaemia and with iatrogenic hypoglycaemia associated with excess insulin or oral hypoglycaemic agents. It is characterised by profuse sweating, anxiety and panic, or an unnatural detached feeling similar to depersonalisation, together with feelings of hunger, tachycardia, tremor and paraesthesia. All are attenuated by adrenergic and cholinergic blockade. Speech and visual disturbances, confusion, fatigue and an ataxic gait are also found. The first group of symptoms is ascribed to the autonomic nervous system, though with the exception of tachycardia all occur with hypoglycaemia in totally sympathectomised patients. Angina may be precipitated if coronary artery disease exists.

When seen in insulin-treated diabetes mellitus, subacute neuroglycopenia is referred to as hypoglycaemic unawareness (see under Brain damage in diabetes). It is characterised by a reduction in spontaneous movements and speech, somnolence, poor performance at habitual tasks, memory impairments and behaviour that is out of character. Patients

may become disinhibited, foolhardy or aggressive in manner, closely resembling alcoholic intoxication. Others become apathetic and withdrawn, with slurred speech and somnolence. The degree of functional impairment is out of proportion to subjective discomfort, and the person typically lacks realisation of the changes within himself. In rare instances, insulin-induced hypoglycaemia results in offending, in which case it constitutes grounds in UK law for a 'sane' (or 'non-insane') automatism (Fenwick 1990).

Brief episodes of unconsciousness and provocation of seizure activity with automatisms may occur in both acute and subacute neuroglycopenic syndromes. Occasionally focal neurological disturbances such as diplopia, hemiparesis or dysphasia may be seen without obvious diffuse cerebral disturbance. If normoglycaemia is not restored, progression to stupor, coma or death from cerebral oedema may occur.

Chronic neuroglycopenia

Chronic neuroglycopenia is rare and virtually confined to patients with insulinomas and patients with diabetes mellitus treated overzealously with insulin. It is characterised by the insidious development of personality change, poor memory and intellectual deterioration resembling dementia or psychosis with paranoid features. Emotional changes may be prominent, with irritability, apathy or emotional lability. The course may be punctuated by episodes of acute or subacute neuroglycopenia. The symptoms and signs are unaltered on the temporary restoration of normoglycaemia but permanent removal of the cause may lead to long-term improvement over a year or more (Marks 1981a).

Glucose passes through the blood-brain barrier via a facilitated transport system using specific glucose transporter proteins. Blood glucose is an important factor in determining the rate of glucose transport and adaptation develops in the face of prolonged hyperglycaemia or hypoglycaemia. This explains in part why diabetic patients experience neuroglycopenic symptoms at higher blood glucose levels, and habitually hypoglycaemic patients at lower levels, than normal subjects. It may also explain why apparently healthy people with no discernible abnormality of glucose homeostasis suffer postprandial symptoms at blood glucose levels tolerated without difficulty by most.

Hypoglycaemic episodes are associated with a wide range of underlying disorders, including severe liver, renal, cardiac and respiratory failure, sepsis, starvation including anorexia nervosa, hypopituitarism, Addison's disease and hypothyroidism. Important to psychiatry are the toxic and drug-induced causes. Alcohol may provoke a reactive hypoglycaemia and salicylates, quinine, haloperidol, beta-blockers, the sulphonylureas and insulins, and many others have been associated with drug-induced hypoglycaemia. Insulinomas are a rare but important cause of hypoglycae-

mia because they may produce a wide range of clinical pictures that are usually intermittent and because there may be normal health between attacks, making diagnosis often very challenging. Other causes, less likely to be seen by psychiatrists, include glycogen storage disease, hereditary fructose intolerance, galactosaemia, carnitine deficiency and disorders of gluconeogenesis.

Alcohol-induced hypoglycaemia

Hypoglycaemia may occur in response to various drugs and poisons of which alcohol is the most important. Alcohol exerts its hypoglycaemic effect mainly by inhibiting gluconeogenesis. It specifically inhibits gluconeogenesis from lactate but not from pyruvate, alanine or glycerol and it does not affect glycogenolysis. Hepatic glycogen stores are rarely sufficient to replace glucose used by insulin-independent tissues such as the brain for more than 8 hours. Consequently, hypoglycaemia most commonly occurs after this time, typically in the chronically alcohol dependent, 6–36 hours after a large intake, and it may first show itself by inducing coma. Sometimes it develops sooner, when it may be overlooked in the face of obvious intoxication. Recovery is usually prompt after the administration of glucose. It is possible that the condition accounts for a considerable number of deaths in alcoholic subjects.

Recurrent attacks are rare but have been reported (Fredericks & Lazor 1963; de Moura *et al.* 1967), usually in those with a long history of alcohol dependency. Arky *et al.* (1968) drew attention to the severe alcohol-induced hypoglycaemia liable to occur in insulin-dependent diabetics. They reported five patients who had repeatedly been admitted to hospital following alcohol-induced hypoglycaemic episodes; two died without recovery from coma and three were left with permanent memory impairments or dementia.

Meal-induced hypoglycaemia

Mild hypoglycaemia with symptoms resembling acute neuroglycopenia occurring after ingestion of food, but not provoked by fasting, are common. These symptoms occur more often in asthenic and emotionally labile persons, and may be associated with minor psychiatric instability in a manner which initiates a vicious circle. Exercise may provoke or aggravate the symptoms, but food or glucose do not bring decisive relief. Between attacks the patient often reports that he feels run down and is functioning below his optimum. The now-discredited oral glucose test, which has a high false-positive rate (>50%), was previously widely used in the assessment of postprandial hypoglycaemia and led to an epidemic of non-hypoglycaemia across the developed world from the 1950s to the 1980s (Jager & Young 1974). However, the failure of this classification to either aid diagnosis or provide a better understanding of the underlying

pathophysiology has led to its demise (Service 1995). No specific treatment is indicated for individuals with symptoms occurring after food ingestion other than advice to avoid provoking foods. Some individuals who are susceptible to even mild lowering of their blood glucose may have a defect in blood–brain glucose transport or neurotic personality traits (Genter *et al.* 1994; Jager & Young 1974) but do not have detectable abnormality of glucose homeostasis (Marks & Teale 2001).

Factitious hypoglycaemia

Surreptitious use of insulin or sulphonylureas to induce hypoglycaemic symptoms can pose a difficult diagnostic problem. It is seen predominantly among those working in health-related occupations, more often in women, and in close relatives of diabetics who have access to their medications. It has also been noted among teenage female diabetics who misuse their insulin (Anon. 1978). Hypoglycaemia may be induced for the benefit of the symptoms experienced or as part of attention-seeking behaviour. Sometimes it may occur in association with Munchausen's syndrome, with patients submitting to laparotomy and even subtotal pancreatectomy.

Presentation is with erratically occurring neuroglycopenic symptoms suggestive of insulinoma. Many patients are admitted in coma. Scarlett *et al.* (1977) described seven subjects with factitious hypoglycaemia in whom symptoms had been present for 2 months to 6 years. Two had had subtotal pancreatectomies before the true cause was discovered; one had been diagnosed with diabetes 17 years previously, probably erroneously; and two had given insulin to their children, one with a fatal result. Another described the exquisite pleasure of going to sleep not knowing whether she would regain consciousness, after injecting insulin.

Jordan *et al.* (1977) described patients abusing sulphonylurea who presented in a similar manner. They estimated that factitious hypoglycaemia was at least as common as insulinomas. Inappropriately raised plasma insulin during hypoglycaemic episodes occurs in both insulin and sulphonylurea abuse, although low C-peptide levels occur only with insulin use. After oral hypoglycaemic agents, C-peptide levels are likely to be raised as a result of β -cell stimulation, a picture that can be virtually indistinguishable from insulinoma. Diagnosis must then be made by demonstrating the drugs in the blood or urine (see Table 10.2).

Marks (1981a) describes a separate group of patients, also paramedical workers or relatives of diabetics, who present with attacks simulating acute neuroglycopenia, sometimes gradually proceeding to coma. However, blood glucose and electroencephalography (EEG) remain normal throughout the episodes. Recovery occurs spontaneously or may be provoked by saline injection. The situation is considered to represent a conversion disorder.

Insulinomas

Insulinomas are rare, occurring in 4 per million person-years (Service 1991). Benign adenomas of the pancreatic islet cells are the most common cause, occurring in the body and tail of the pancreas in two-thirds. Occasionally ectopic insulinomas occur in the vicinity of the duodenum or porta hepatis. Less than 10% are malignant. Approximately 6% occur as part of multiple endocrine neoplasia (MEN) syndrome type 1, a familial disorder associated with adenomas of the parathyroid, pituitary or other endocrine glands (see under Hyperparathyroidism, later in chapter). They are slightly more common in women and may occur at any age.

Episodes of odd behaviour and disturbances of consciousness are the main reasons for referral. Symptoms have commonly been present for months or years by the time the diagnosis is made, sometimes for as long as 30 years. Very occasionally, long remissions may be detected in the histories. Almost any psychiatric syndrome may be simulated, depending quite probably on the individual's constitution. The detailed content of attacks may differ from one occasion to another and diagnostic confusion is common. The essential clue usually lies in the episodic and recurrent nature of the attacks. An added difficulty is that organic features are not always evident, the change of consciousness sometimes being so slight that it passes unnoticed except to those familiar with the patient.

Typically attacks of subacute, or less often, acute neuroglycopenia occur. They gradually increase in frequency, initially occurring at intervals of several weeks or months but by presentation are often occurring several times per week. Attacks may commence abruptly, or with slowly worsening weakness, ataxia and confusion. Sweating, nystagmus, inco-ordination or focal neurological signs such as hemiparesis or positive Babinski responses may be seen during an attack. Coma is rare except in the most severe episodes. Initially attacks are commonest at midday, though later they occur more characteristically before breakfast and during the night. Only one-quarter of patients give a clear history of a relationship to fasting and only 10% to exercise, while relief by eating is even more rarely noticed by the patient (Marks 1981b). Typically the patient has complete amnesia for the content of the attacks, and occasionally for additional periods during which behaviour was seemingly normal. Between attacks he usually feels quite well. In a small proportion, chronic neuroglycopenia may occur with progressive mental or physical disability and little or no history of episodic disturbance.

Cases from the literature illustrate some of the diagnostic difficulties.

A 44-year-old man suffered from attacks of confusion with bizarre behaviour over a 5-year period. Each lasted from a few minutes to several hours and increased in frequency until they were occurring four to five times per week. He

had partial or complete amnesia for the attacks, which were initially interpreted as fugue states. On one occasion whilst driving he started driving recklessly with complete disregard for his passenger. On another he wandered semi-confused at work for 2 hours, conducting coherent conversations with some people but ultimately removed his shirt and stared foolishly at people who tried talking to him. An episode when he clenched an axe in a menacing manner, after chopping wood, and wandered around his neighbourhood with a dazed expression led to his admission. In other episodes he was described as being pale, sweating, appearing limp and unsteady with drunken behaviour and double vision. During prolonged starvation it was possible to demonstrate intermittent disturbances of awareness that became progressively more marked even though the blood sugar values were essentially unchanged. Periods of acute motor excitement with confusion and aggressive behaviour could similarly begin and end without significant changes in the blood sugar (Romano & Coon 1942).

A 27-year-old man was referred as a psychiatric emergency with bouts of aggressive and destructive behaviour. During attacks he was disorientated with inappropriate behaviour, sweating and a violent tremor. Following them he had no recollection of what had occurred. He had a history of learning difficulties and of head injury at the age of 18 years. His father had a history of similar bouts of violent behaviour. The initial differential diagnosis included aggressive psychopathy, mental impairment with behaviour disturbance, and post-traumatic epilepsy. Prolonged fasting provoked a typical attack at 16 hours, associated with hypoglycaemia and relieved by glucose. At laparotomy multiple islet-cell tumours were found. A diagnosis of multiple endocrine adenomatosis (pluriglandular syndrome) was made as hyperparathyroidism was also present. His father had died with 'islet-cell-secreting tumour of the pancreas and calcification of the kidneys' (Carney *et al.* 1971).

Differential diagnosis of insulinomas

The following psychiatric and neurological conditions may often be suspected before the diagnosis of an insulinoma is made.

- Anxiety disorders may be suggested by episodes of anxiety, panic and depersonalisation.
- Personality disorder may be suggested by a history of episodes of aggressive or antisocial conduct, for which the patient claims amnesia or only a hazy recollection.
- Manic-depressive or schizophrenic psychoses may very occasionally be diagnosed. Rare cases of insulinoma have been reported to present with acute depressive psychoses, no doubt as a result of individual predisposition.

- Dementia may be closely simulated in cases with chronic deterioration of intellect and personality. Superimposed episodes of acute and transient disturbance may resemble the step-like course of multi-infarct dementia.
- A space-occupying lesion may be suspected when attacks provoke epilepsy, or when headache and focal neurological symptoms accompany clouding of consciousness. Carotid artery stenosis may be suggested by attacks of dysphasia or hemiplegia, or vertebrobasilar insufficiency when vertigo and diplopia are prominent features.
- Epilepsy is a relatively rare form of presentation of hypoglycaemia except in childhood. However, any episodic and recurrent neurological disorder is likely to raise the question of epilepsy, and the content of attacks may closely resemble the automatisms of complex partial seizures.
- Intoxication with other metabolic disorders such as uraemia or liver failure may be closely simulated, or endocrine disorders such as thyrotoxicosis, hypoparathyroidism or pheochromocytoma.

Rare cases may present with peripheral neuropathy. Narcolepsy may sometimes be considered, or attacks of somnolence may suggest Kleine-Levin syndrome. Angina, vasovagal attacks, orthostatic hypotension and Stokes-Adams attacks may also be considered.

Investigation of hypoglycaemia

Spontaneous hypoglycaemia should be considered in anyone who presents with an episode of subacute neuroglycopenia, even if there may be an alternative explanation for the symptoms. A blood sample should be obtained when the patient is symptomatic, a process that may require training the patient or a friend or relative in collecting a capillary blood sample (Gama *et al.* 2003). Most patients with episodic spontaneous hypoglycaemia will have at least one overnight (18-hour) fasting blood glucose concentration below 2 mmol/L, when measured on three separate occasions.

The prolonged fast or 72-hour fast test has been advocated as the test of choice for investigating hypoglycaemia. It should be conducted in hospital under careful supervision. During the fast the patient is allowed to drink non-caloric and caffeine-containing drinks and is encouraged to be ambulant during the day. Blood glucose, insulin, C-peptide and proinsulin are tested 6 hourly until blood glucose is less than 3.5 mmol/L, when sampling is reduced to 1–2 hourly and the patient tested regularly for signs or symptoms of neuroglycopenia. The fast should be terminated if the blood glucose falls below 2.5 mmol/L in association with symptoms or signs of neuroglycopenia or if neither symptoms of neuroglycopenia nor episodes of hypoglycaemia have occurred at 72 hours. Glucose, insulin, C-peptide, proinsulin, β -hydroxybutyrate and sulphonylurea are tested at the end of the fast and plasma glucose response to glucagon before refeeding. When a deficiency is suspected, plasma

cortisol, growth hormone or glucagon should also be measured at the beginning and end of the fast.

Interpretation of the findings of the 72-hour fast is shown in Table 10.2. To complicate interpretation, healthy, young, lean women may have plasma glucose concentrations of 2.5 mmol/L or even less following prolonged fasting in the absence of symptoms (Service 1999). Other provocation tests include the exercise test; the mixed meal test, the C-peptide suppression test and tolbutamide test are also occasionally used.

Electroencephalography

Sequential EEG changes were recorded during the course of insulin coma therapy, which was previously used for the treatment of schizophrenia. The EEG response to hypoglycaemia varies considerably between individuals, though is relatively stereotyped within individuals. In general, the correlation between symptoms and EEG change is closer than between symptoms and blood sugar levels. The earliest change to be detected is the appearance of delta rhythms on overbreathing. Spontaneous theta and delta waves then occur, and later asynchronous irregular waves and a flattened tracing. The abnormalities are often most marked over the temporal lobes. In hypoglycaemic coma the EEG consists of high-voltage delta waves as in other metabolic comas. After severe hypoglycaemic episodes, abnormalities may persist in the EEG for several days before reverting to normal.

Treatment of hypoglycaemia

The aims of treatment of hypoglycaemic disorders are twofold: to relieve neuroglycopenic symptoms by restoring normal plasma glucose levels and to treat the underlying cause. Neuroglycopenic symptoms can be relieved by oral glucose tablets, which should be carried by patients awaiting investigation when hypoglycaemic attacks are known to occur; during more severe attacks glucose may be given intravenously as a 5 or 10% solution or as a bolus of 50% solution.

Treatment of the underlying cause depends on the specific causal mechanism. Causative medications should be withdrawn, patients with alcohol dependency advised on the dangers of hypoglycaemia and individuals suspected of insulinomas should be referred to centres specialising in the management. The possibility of coincident hypoadrenalism or hypopituitarism must then be borne in mind, and parenteral hydrocortisone considered.

Outcome of hypoglycaemia

The immediate outcome for most attacks is excellent. The symptoms usually resolve spontaneously even without

specific treatment. Sometimes, however, neurological and psychiatric manifestations may outlast the actual period of hypoglycaemia. Dysphasia, hemiparesis and stupor have been reported to persist for hours or even weeks after restoring the blood sugar to normal, also negativism, restlessness, apathy and prolonged behaviour disorder (Markowitz *et al.* 1961). Such disturbances are thought to rest on a vascular basis that ultimately resolves. Recovery from hypoglycaemic coma may similarly be delayed for hours or even weeks in occasional cases. After prolonged coma recovery may be incomplete, with evidence of permanent brain damage and dementia (Arky *et al.* 1968).

The outcome after surgery for insulinoma is excellent in the great majority of cases. The typical patient who has presented with intermittent episodes of neuroglycopenia ceases to have such attacks, whatever form they have taken, and normal health is restored.

While this is the experience of most observers, occasional reports have indicated a less favourable picture on prolonged follow-up. Markowitz *et al.* (1961) followed six early cases after a lapse of 25 years, and found that five had shown either persisting or newly acquired mental disturbances in the interim. These were sometimes severe, including manic-depressive psychosis, irrational or erratic behaviour and other aberrations of personality, and were thought possibly to represent the aftermath of brain damage sustained during the hypoglycaemic episodes. A surprisingly high incidence of peptic ulceration and haemorrhage had also developed, even though ulcerogenic pancreatic tumours had not appeared to be present.

The rarer presentations in the form of chronic psychosis or intellectual deterioration may be expected to improve to some degree after operation, but here recovery is seldom complete. In these cases, as after prolonged episodes of hypoglycaemic coma, irreversible brain damage often proves to have occurred. Thus among 100 patients with psychosis or 'long-term insanity' in the detailed review by Laurent *et al.* (1971), 37 showed little or no improvement after removal of the hypoglycaemic tumour. The longer the duration of symptoms before the diagnosis, the greater was the risk of permanent mental disability.

Cerebral pathology of hypoglycaemia

Pathological changes in the brain following acute episodes of hypoglycaemia have mainly been studied in cases following insulin coma therapy. The brain may show oedema and vascular congestion, whilst survival after profound hypoglycaemic coma may be associated with ventricular dilatation, cortical atrophy and hippocampal atrophy. Neurones show ischaemic cell changes and associated gliosis. Cell damage may occur in scattered foci, but is more typically laminar with emphasis on the third and fifth layers (Brierley 1981). Relative sparing of the visual cortex is usual, but the corpus

Table 10.2 Diagnostic interpretation of the results of a 72-hour fast.*

Diagnosis	Symptoms or signs	Glucose [†] (mg/day)	Insulin ^{‡§} (μU/ml)	C-peptide ^{¶¶} (nmol/litre)	Proinsulin [§] (pmol/litre)	β-Hydroxy-butyrate (mmol/litre)	Change in glucose ^{**} (mg/dl)	Sulphonylurea in plasma
Normal	No	≥40	<6	<0.2	<5	>2.7	<25	No
Insulinoma	Yes	≤45	≥6 ^{††}	≥0.2	≥5	≤2.7	≥25	No
Factitious hypoglycaemia from insulin	Yes	≤45	≥6 ^{‡‡}	<0.2	<5	≤2.7	≥25	No
Sulphonylurea-induced hypoglycaemia	Yes	≤45	≥6	≥0.2	≥5	≤2.7	≥25	Yes ^{§§}
Hypoglycaemia mediated by insulin-like growth factor	Yes	≤45	≤6	<0.2	<5	≤2.7	≥25	No
Non-insulin-mediated hypoglycaemia	Yes	≤45	<6	<0.2	<5	>2.7	<25	No
Inadvertent feeding during the fast	No	≥45	<6	<0.2	<5	≤2.7	≥25	No
Non-hypoglycaemia disorder	Yes	≥40	<6	<0.2	<5	>2.7	<25	No

* Measurements are made at the point the decision is made to end the fast.

[†] Sequential plasma glucose measurements in the hypoglycaemia range fluctuate. Plasma glucose levels ≤45 mg per decilitre at the time a decision is made to end the fast may rise to as much as 50 mg per decilitre when the fast is factually ended approximately one hour later. Plasma glucose levels may be as low as 40 mg per decilitre during prolonged fasting in normal women. To convert values to millimoles per litre multiply by 0.05551.

[‡] Measured by double-antibody radioimmunoassay (lower limit of detection, 5 μU per millilitre). To convert values to picomoles per litre, multiply by 6.0.

[§] In normal subjects plasma insulin, C-peptide, and proinsulin levels may be higher if the plasma glucose levels is ≥60 mg per decilitre.

[¶] Measured by the immunochemiluminometric technique (lower limit of detection, 0.033 nmol per litre).

^{||} Measured by the immunochemiluminometric technique (lower limit of detection, 0.2 pmol per litre).

^{**} In response to intravenous glucagon (peak value minus value at the end of fast). To convert values to millimoles per litre, multiply by 0.05551.

^{††} Ratios of insulin to glucose are of no diagnostic value in patients with insulinomas.

^{‡‡} Plasma insulin levels may be very high (>100 μU per millilitre or >1000 μU per millilitre) in factitious hypoglycaemia from insulin.

^{§§} Unlike the first generation of sulphonylurea drugs, which were easily measured, second-generation drugs are not.

striatum and the hippocampi appear to be especially vulnerable, as in cerebral hypoxia (see Chapter 4, Neuronal death). However, in hypoglycaemia the cerebellar Purkinje cells appear to be less affected (Richardson *et al.* 1959).

Hypothyroidism

Hypothyroidism remains of great importance in psychiatric practice and is notorious for leading to mistakes in diagnosis. The prevalence, nature and clinical course of the behavioural and psychological disturbances associated with hypothyroidism (myxoedema) were first described in a report by the Clinical Society of London (1888). This described some degree of mental disturbance, ranging from irritability and agoraphobia to dementia and melancholia in almost all untreated patients with hypothyroidism. Subsequently, it has been recognised that the effect of prolonged hypothyroidism on brain function may be severe and potentially irreversible. Furthermore, on account of its insidious development with minor and often diffuse complaints at first presentation, diagnosis of hypothyroidism may be considerably delayed and isolated case reports of hypothyroid patients presenting with psychiatric manifestations continue to appear in the literature.

The widespread availability of cheap reliable laboratory tests for quantification of thyroid hormone levels has objectified diagnosis, although this has also led to the identification of a larger group of patients with biochemically borderline hypothyroidism. These patients have few if any specific symptoms with often ill-defined complaints, and ideal management currently remains unclear. Recent research has also suggested that a group of residual symptoms may remain despite 'adequate' replacement therapy with thyroxine. A number of randomised controlled trials investigating response to treatment with a more physiological combination of tri-iodothyronine and thyroxine have produced conflicting results and the issue of best treatment of residual symptoms currently remains unresolved.

Hypothyroidism is a common condition with an incidence that increases markedly with age, especially from middle age onward. Like hyperthyroidism, it is very much commoner in women than men, in a ratio of approximately 8:1. Classification based on severity subdivides hypothyroidism into mild and overt forms: in the former, serum thyroid-stimulating hormone (TSH) alone is raised; in the latter, a reduction in serum free thyroxine is also seen. The large Whickham study identified raised serum TSH (mild or overt hypothyroidism) in 7.5% of women and 2.8% of men in a UK community population (Tunbridge *et al.* 1977). Subsequent studies have found similar figures with incidences rising markedly with age, up to 21% in a female group aged over 74 years in one study, with the ratio of mild to overt hypothyroidism ranging from 5:1 to 15:1 (Roberts & Ladenson 2004).

Physical features

Overt hypothyroidism is associated with a familiar set of symptoms and signs. The appearance is characteristic, with a pale puffy complexion and baggy eyelids. The skin is dry and rough, with a non-pitting oedematous appearance over the face and limbs and in the supraclavicular fossae. Hair loss may have been noticed and hair may have become lank and dry in texture. Speech is slow, and the voice often coarse, thick and toneless. The whole disposition of the patient tends to be sluggish and inert. The pulse is usually slowed and angina, congestive heart failure or pericardial effusion may occur. Appetite is diminished, the patient is often constipated and ileus and intestinal pseudo-obstructions may occur. Hearing, taste and smell may be impaired due to deposits of mucoid material. Intolerance of cold is often a prominent early complaint. Menorrhagia is common in women and impotence in men. Vague generalised aches and pains of a rheumatic nature may occur. Very occasionally muscular weakness may be the initial manifestation.

Neuropsychiatric features

Initially psychological changes are non-specific and ill-defined. Cognitive disturbances include the inability to concentrate, poor attention, bradyphrenia, calculation difficulties and difficulty understanding complex questions. Memory is often affected from an early stage, with failure to register events and forgetfulness for day-to-day events. Memory for remote events may also deteriorate in chronic cases. Psychomotor retardation is seen and ready fatigability is conspicuous. With chronic disease, the ability to perform everyday routine tasks is decreased and such tasks take a progressively longer time to complete. Patients become less concerned about and responsive to others, and there is marked inability to sustain mental exertion. The patient also becomes less capable of learning and performing new tasks. Speech is reduced and perseverations are frequently seen. Alterations in the accuracy of perception may also develop with a tendency to illusion formation, and later hallucinations in the visual or other modalities and may lead to the development of paranoid ideas. Historical accounts describe a progression to increasing drowsiness, with lethargy and difficulty in arousal.

In the earlier stages the patient is subjectively aware of such changes, and may complain of poor memory or difficulty concentrating. The profound loss of interest and initiative carries the risk of delaying medical attention. Because of these changes in attention and concentration, slowing of thought and actions, and reduced responsiveness to others, the diagnosis may be confused with one of depression. Indeed, as discussed below, depression develops more commonly in hypothyroidism though irritability is also a fre-

quent feature, and some patients become markedly agitated and aggressive.

Mild hypothyroidism

Several studies have suggested that mild symptoms of hypothyroidism are commoner and scores on measures of depression and anxiety higher in patients with subclinical hypothyroidism than in age-matched controls. These findings, however, are inconsistent with other studies that have found no significant differences (Cooper 2001). A number of small studies have also examined the effect of mild hypothyroidism on memory and concluded that small improvements in function are associated with thyroxine therapy in this group. However, the strength of the evidence for these associations is small, and a recent consensus statement indicates that the data supporting the association of subclinical thyroid disease with symptoms or adverse events are few (Surks *et al.* 2004).

In this review of the literature, the subclinical hypothyroid group comprises those with TSH above or below 10 mIU/L. The authors do not recommend routine treatment of patients with TSH below 10 mIU/L unless symptoms compatible with hypothyroidism are also present. In the symptomatic condition, it is recommended that a treatment trial extending to several months should be considered at the clinician's discretion, with continuing treatment predicated by clear symptomatic benefit. Measurement of TSH levels every 6–12 months is advised to monitor for progression to overt hypothyroidism. In the group with TSH above 10 mIU/L, treatment with levothyroxine is considered reasonable in view of the higher conversion rate to overt hypothyroidism, although the evidence that such treatment leads to reduced cholesterol levels or symptoms is deemed inconclusive. The exception is pregnant women, who should be referred for expert advice.

Schizophrenic and affective psychoses

It is against the background of the neuropsychiatric changes described above that the more severe psychiatric disturbances of hypothyroidism develop. The psychoses that develop are non-specific and may mimic the psychoses seen in schizophrenia or the affective psychoses. They may develop acutely or run a subacute course over several weeks or months. Importantly, careful history and examination will often reveal a few stigmata of hypothyroidism (Whybrow & Bauer 2000) and assessment of cognitive function may aid differential diagnosis. Though confusion may occur in acute schizophrenia, visual hallucinations with marked and persistent cognitive disturbances are rare. The only unifying feature, upheld by many observers, is the frequency of a paranoid colouring whatever form the psychosis may take (Asher 1949).

In Asher's (1949) classic paper on 'myxoedematous madness' in 14 patients, five showed an organic reaction with hallucinations and persecutory ideas, five the picture of schizophrenia with a marked paranoid colouring, two presented as advanced dementia, and two with depressive features.

Organic psychoses usually show the features of delirium, with florid delusions and hallucinations, mental confusion and impairment of consciousness. Delusions of persecution may be gross and bizarre. Auditory hallucinations appear to be particularly common. Dementia develops as an extension of the mental impairment characteristic of the condition generally. Depressive and schizophrenic psychoses may or may not be accompanied by organic mental features, though the latter are usually found when sought with care. Paranoid symptoms again figure prominently. Schizophrenic psychoses will in general be coloured by mental slowing, and often include features indicative of organic cerebral impairment.

Few behavioural studies have been conducted in patients with hypothyroidism unselected for psychiatric disorder and therefore the incidence of psychosis in hypothyroidism is difficult to determine. In the early 1888 review before the availability of treatment, it was of the order of 15%. However, our ability to reliably detect early-onset cases through the widespread availability of laboratory testing has reduced current levels to considerably below this.

Depressive syndrome

Depressive affect has been reported as a frequent association with hypothyroidism (Whybrow *et al.* 1969) and a regular feature of early case series. Despite this there are few good studies describing prevalence rates.

Several of the metabolic and behavioural changes seen in hypothyroidism are common to depression, suggesting that changes in the pituitary–thyroid system may play a role in the modulation of mood. The most common abnormality in thyroid function testing among patients with depression is a mild elevation in serum thyroxine concentration, which falls with clinical response to treatment (Whybrow & Bauer 2000). Serum TSH response to thyrotropin-releasing hormone is blunted in 25% of depressed patients and the nocturnal surge of TSH is lost in depression, returning to normal with recovery (Whybrow & Bauer 2000).

Mild hypothyroidism is also more frequent in rapid cycling bipolar disorder, occurring in up to 25% of cases. Thyroxine supplementation of established treatment for bipolar disorder has been shown to reduce the number of episodes (Whybrow & Bauer 2000).

Neurological accompaniments

Ankle reflexes may be slowed with marked delay in the relaxation phase, though these are not specific and have also been described in diabetes mellitus and anorexia nervosa

(Larner 1995). Muscle weakness is a very common complaint that often does not correlate with biochemical severity and may persist despite therapy (Duyff *et al.* 2000). A predominantly sensory axonal peripheral neuropathy and proximal neuropathy and more rarely focal muscle enlargement or wasting may also occur (Askmark *et al.* 2000). Sleep apnoea may occur as a result of obesity or upper airway obstruction.

Jellinek (1962) drew attention to the occurrence of fits, faints, and cerebrovascular accidents in patients with hypothyroidism. Four patients were reported with generalised seizures that responded to thyroid replacement, others with attacks of syncope, and others with unusual confusional episodes suggesting temporal lobe dysfunction. Cerebrovascular accidents and episodes of previous transient cerebral ischaemia were found to have occurred in several of his patients, and hypothyroidism is known to be associated with a coagulopathy and raised risk of cardiovascular disease (Roberts & Ladenson 2004).

Cerebellar ataxia is an uncommon consequence of advanced hypothyroidism that does not seem to correlate with biochemical severity (Barnard *et al.* 1971). Jellinek and Kelly (1960) drew attention to the disorder in a description of six cases presenting with cerebellar disturbance in the form of ataxia, tremor, dysarthria and nystagmus that remitted promptly with replacement therapy. Though the aetiology remains unclear, the prompt response to therapy suggests a metabolic rather than structural cause in the majority of cases.

Hypothyroid coma is a grave condition which carries a high mortality. It typically develops in association with

superimposed infection, surgery or trauma (Kaminski & Ruff 1989). It should be suspected in any patient with severe impairment of consciousness and hypothermia. The skin feels icy cold, and a low-reading rectal thermometer is required to confirm the hypothermia. Respiration may be sluggish, and cardiac failure or dysrhythmia is a feature of serious significance.

Investigations

As with hyperthyroidism, it is essential to confirm the diagnosis by laboratory tests before starting treatment. The total and free thyroxine levels are low, although serum triiodothyronine may be normal. Elevated plasma TSH will indicate primary thyroid failure, whereas normal basal levels will suggest a pituitary origin. The latter is confirmed by an absent, subnormal or delayed response to thyrotropin-releasing hormone. The estimation of circulating autoantibodies to thyroglobulin and thyroid peroxidase may help to establish the cause, for example Hashimoto's thyroiditis.

The serum cholesterol is elevated, the heart is usually enlarged and the ECG shows a low-voltage tracing with flattened or inverted T waves. The EEG shows lowered voltage and slowing of the dominant frequencies; occasionally it is normal despite severe hypothyroidism but this is rare. The protein in the cerebrospinal fluid may be moderately raised.

Neuropsychology

The neurocognitive deficits in hypothyroid adults are listed in Table 10.3.

Table 10.3 Neurocognitive deficits in hypothyroid adults. (From Dugbartey 1998.)

Cognitive domain	Treatment outcome	Psychometric test
General intelligence	Not generally affected	WAIS, WAIS-R, DRS
Complex attention and concentration	Improvement after 5–7 months Equivocal change 5–10 months	PASAT, SDMT TMT (Part A and B)
Memory	Improvement No change (treatment may prevent further decline)	Inglis paired associates learning test CVMT, FMT, RCFT, SRT, WMS
Perceptual and visuospatial function	Improvement No improvement	WAIS-R (Block design and Object assembly subsets) Cube copying
Language (expressive)	No improvement	Word fluency (Animals)
Language (receptive)	Not available	Word discrimination, oral reading
Executive/frontal system	Not available No change	Go-No Go, Word fluency, Luria's m's and n's Porteus mazes
General screening	No change Progressive decline	Modified MMSE MMSE
Motor function	No change	Grip strength

CVMT, Continuous Visual Memory Test; DRS, Dementia Rating Scale; FMT, Milner Facial Memory Test; PASAT, Paced Auditory Serial Addition Task; RCFT, Rey-Osterrieth Complex Figure Test; SDMT, Symbol Digit Modalities Test; SRT, Selective Reminding Test; TMT, Trailmaking Task; WAIS(-R), Wechsler Adult Intelligence Scale (-Revised); WMS, Wechsler Memory Test.

Differential diagnosis

Not uncommonly, hypothyroidism is first diagnosed only after a patient has been symptomatic for a considerable time. The suspicion of hypothyroidism is usually derived from the characteristic facial appearance or other physical symptoms and signs, but unless the disorder is specifically considered these may easily be overlooked. In the 14 cases reported by Asher (1949), all with florid mental illnesses, the hypothyroidism had been missed by the referring doctor in every case. In the more severe psychotic illnesses, organic features are usually evident in the mental state but not invariably so.

Even without overt evidence of hypothyroidism, psychiatric patients may warrant investigation if they have a history of thyroidectomy or of having required thyroid medication in the past. These were the factors that prompted investigation in 5 of 18 patients surveyed by Tonks (1964) in a psychiatric hospital. Patients on long-term lithium therapy are also at increased risk of developing hypothyroidism and require regular monitoring of serum TSH levels.

Aetiology of mental disturbances

The specific pathophysiology responsible for the behavioural and emotional disturbances seen in hypothyroidism remains unknown. Early investigations showed a 38% reduction in cerebral blood flow and 27% reduction in oxygen and glucose consumption in patients with hypothyroidism (Scheinberg *et al.* 1950). An associated near-twofold increase in cerebrovascular resistance led to the hypothesis that cerebral hypometabolism was a consequence of increased cerebrovascular resistance and reduced cardiac output rather than altered cerebral metabolic demands (Sokoloff 1953; O'Brien & Harris 1968), with the relative cerebral hypoxia worsened by frequently coexistent anaemia.

Smith and Ain (1995) using ^{31}P magnetic resonance spectroscopy reported a relative increase in frontal phosphocreatine/inorganic phosphate ratio in response to treatment of hypothyroidism, suggesting a treatment-related increase in frontal lobe metabolism; in contrast, Constant *et al.* (2001) using positron emission tomography (PET) showed globally reduced neural metabolism in hypothyroidism that they argued could not be explained by increased vascular resistance alone. Nuclear receptors for tri-iodothyronine are prominent in the brain particularly in neurones and are found in high concentrations in the amygdala and hippocampus, regions associated with modulation of mood, and in low concentrations in the brainstem and cerebellum (Ruel *et al.* 1985). The question of whether the cerebral hypometabolism seen in hypothyroidism is a consequence of a direct action of thyroid hormones on neurones or is secondary to altered cerebral blood flow therefore remains unanswered and will perhaps await the development of techniques to directly measure CNS thyroid metabolism *in vivo*. Nevertheless, the associated mental symptomatology can be largely

ascribed to changes in cerebral metabolism, regardless of cause. Such changes are also reflected in the EEG findings described above, and these can also be observed to improve with substitution therapy.

Cases of major affective disorder and schizophrenia are likely to be determined by both organic factors and genetic and environmental factors. In the rare examples where organic features are entirely absent from the mental state, the cerebral metabolic defect has probably served merely as a precipitant. However, the situation is not entirely straightforward, since patients with purely depressive symptomatology with no evidence of hypothyroidism have been found to respond to thyroxine, often after other forms of treatment have failed entirely (Bauer *et al.* 1998).

Outcome of mental disturbances

The treatment of hypothyroidism is usually highly rewarding, with behavioural disturbances responding well to adequate thyroxine therapy, although supplementation with an antidepressant or neuroleptic is often initially helpful. The great majority of patients with serious psychiatric developments can also be expected to respond, even those with overt dementia, provided too long an interval has not elapsed. However, Jellinek (1962) stressed that several of his cases were left with measurable defects of intellect and memory after being rendered euthyroid, mostly those who had remained undiagnosed for very long periods of time or where treatment had been inadequate.

Where response to thyroxine is concerned, the frankly organic psychoses can generally be expected to do better than psychoses with predominantly 'functional' symptomatology. This was confirmed by Tonks (1964), who surveyed 18 hypothyroid patients in a psychiatric hospital during a period of treatment with thyroid preparations alone; the proportion that made complete and lasting recoveries was much higher among patients who showed evidence of disturbance of consciousness, by way of disorientation or confusion, than among those who did not. The duration of the illnesses was also important, in that no patient with a mental illness exceeding 2 years had a satisfactory response to the trial of thyroid replacement therapy alone. The only clearly organic condition that failed to respond was a patient with chronic progressive dementia and aphasia of 7 years' duration. In most patients cognitive dysfunction also improves markedly with treatment (Haggerty *et al.* 1990; Osterweil *et al.* 1992). However, studies have also suggested that residual symptoms remain in patients on 'adequate' thyroxine treatment, raising the possibility of augmenting therapy with tri-iodothyronine.

Additional measures in the form of phenothiazines, antidepressant medication or electroconvulsive therapy may be necessary in psychotic disorders, and particularly so when organic features are absent from the mental state. It must be borne in mind, however, that phenothiazines carry a small

risk of precipitating hypothermic coma in hypothyroid patients, as in an early case reported by Mitchell *et al.* (1959).

It is necessary to introduce thyroxine with caution at the beginning of treatment, especially in the elderly, because of the possibility of myocardial damage. The starting dose of L-thyroxine sodium should not exceed 50 µg daily. If there is no evidence of cardiac failure or angina, this may be increased by 25–50 µg per day every 2–3 weeks until the maintenance dose of 100–150 µg daily is reached.

Very occasionally the initiation of treatment is accompanied by the emergence of psychotic disorder, which interestingly usually takes the form of mania. Josephson and Mackenzie (1980) refer to 18 examples in the literature, 12 being manic illnesses and the others mixed affective or depressive disorders. The symptoms usually began within 4–7 days of starting thyroxine treatment, resolving over 1–2 weeks irrespective of further therapeutic intervention. All recovered completely. Such patients often had a personal or family history of psychiatric disorder and had frequently been depressed or delusional prior to starting treatment.

Replacement with thyroxine and tri-iodothyronine?

Despite 'adequate' therapy with thyroxine, with TSH within the desired range, many hypothyroid patients complain of persistent lethargy and other persisting psychological symptoms. A large community-based study using the general health questionnaire (GHQ) and a validated thyroid symptom questionnaire showed that, compared with controls, 26% more hypothyroid patients with a normal TSH showed caseness, defined as a score of 3 or more on the GHQ. This significant difference persisted after correction for chronic disease, drug use, age and sex (Saruvanan *et al.* 2002). Whether this represents a failure of thyroxine replacement to accurately mimic the normal physiological milieu, is the result of being labelled with a disease, or is due to case ascertainment bias (i.e. individuals with an inclination to complain and seek medical care are more likely to be diagnosed with subclinical hypothyroidism) remains unclear.

A randomised clinical trial has suggested that combined therapy with tri-iodothyronine and thyroxine leads to improved cognitive performance, mood and physiological well-being compared with treatment with thyroxine alone (Bunevicius *et al.* 1999). However, subsequent randomised clinical trials have failed to replicate these findings, leading to suggestions that it is perhaps only patients with complete absence of thyroid function alone who may benefit from combined therapy (Clyde *et al.* 2003; Cooper 2003a; Sawka *et al.* 2003; Walsh *et al.* 2003). Optimum treatment of persistent psychological symptoms and mood disturbance therefore currently remains unclear.

Hyperthyroidism

Hyperthyroidism results from excess of the circulating thyroid hormones thyroxine and tri-iodothyronine. Thyroid hormones regulate energy and heat production, facilitate healthy development of the CNS, regulate somatic growth, puberty, and the synthesis of proteins important in cardiac, hepatic, neurological and muscular functions.

Although there is a rough correlation between levels of circulating hormones and severity of symptoms (Trzepacz *et al.* 1989), individuals, particularly the elderly, may present with widely differing sets of symptoms. Hyperthyroidism has a number of different causes where goitrous enlargement may or may not be present. Graves' disease is the most common cause, though the development of one or more autonomously functioning thyroid nodules is commonly seen in the elderly. There are a number of other rarer causes of hyperthyroidism including forms of thyroiditis and neoplasia, which will not be detailed here. For a comprehensive list see the recent review by Cooper (2003b) or a textbook of medicine.

A large British-based population survey from the 1970s identified unsuspected and undiagnosed hyperthyroidism in 0.5% of women (Tunbridge *et al.* 1977). A more recent survey in the USA found hyperthyroidism in 0.5% of randomly selected individuals, with subclinical or mild hyperthyroidism in a further 0.8% (Hollowell *et al.* 2002). Females are much more commonly affected than males in a ratio of approximately 6:1. Commonest presentation is in the second and third decades of life though the range is wide.

Attention has been directed to the role of stress and emotional disturbance in precipitating hyperthyroidism, in particular Graves' disease, and on the psychological constitution of those who develop the disorder. The onset is often abrupt and may be seen to follow directly upon some stressful event or emotional crisis. It is hard, however, to exclude the possibility that such emotional traumas may themselves have been the by-products of early and unsuspected thyroid overactivity. Gray and Hoffenberg (1985) failed to find an association between stressful life events and the onset of thyrotoxicosis or any cause when compared with a control group of non-toxic goitre. However, Matos-Santos *et al.* (2001) showed significantly more stressful life events with significantly greater impact in the 12 months preceding onset of symptoms in a Graves' disease group than a control group with toxic nodular goitre. These authors argue that Gray and Hoffenberg failed to find an association because they grouped all thyrotoxic patients together rather than looking specifically at Graves' disease, which is associated with an autoimmune aetiology.

Follow-up studies investigating premorbid personality using standardised personality measures suggest that neurotic features are transient rather than indicative of pre-existing personality traits in hyperthyroid patients (Jadresic 1990).

Common psychological accompaniments

Psychological disturbance of some degree is universal with hyperthyroidism. Patients frequently complain of nervousness and fatigue, and appear restless, overactive and irritable, sometimes with hyperacuity of perception and over-reaction to noise. Heightened tension leads to impatience and intolerance of frustration, and emotional lability may develop. Generalised anxiety has been reported in 80% and an association with panic disorder and the earlier 'atypical organic brain syndrome' and 'organic anxiety syndrome' has been described (Kathol *et al.* 1986; Jadresic 1990).

Depression can be prominent and found with symptoms of agitation rather than retardation (Woodbury 1918; Brownlie *et al.* 2000). Kathol *et al.* (1986) found that almost one-third of 29 consecutive patients seen in an endocrine clinic met criteria for major depression. In the elderly, an 'apathetic' hyperthyroidism with anergia and mental slowing occurs, classically presenting without the characteristic eye signs of hyperthyroidism (Thomas 1970). The acute confusional states described as occurring as part of thyroid crises are now rarely seen.

Heightened arousal leads to distractibility and impairment of concentration with difficulty sustaining focused attention. In addition, careful examination may reveal definite cognitive impairments, in the form of difficulty with simple arithmetic or with recent memory of which the patient may be unaware (Whybrow *et al.* 1969). In a survey of the populations of two psychiatric hospitals, comprising a total of over 1200 persons, McLarty *et al.* (1978) found just eight patients with thyrotoxicosis. In six the hyperthyroidism had been unsuspected prior to the survey, and in five it seemed to be contributing to the mental illness.

Psychoses

Psychosis is an uncommon association of hyperthyroidism, which may occasionally be the presenting feature and lead directly to psychiatric referral. A recent study of thyrotoxic psychosis from New Zealand suggested that in contemporary practice approximately 1% of thyrotoxic patients are first diagnosed with a major psychiatric illness (Brownlie *et al.* 2000).

Acute organic reactions accompany 'thyroid crises' and show the typical picture of delirium, usually accompanied by fever. They were formerly one of the commonest forms of major mental illness encountered in the disease, but are now very rare because of modern methods of treatment. They constitute a grave emergency and warrant urgent intervention.

Affective and schizophreniform psychoses are sometimes indistinguishable from their naturally occurring counterparts. A number of reports have suggested that mania is more frequent than depression (Lee *et al.* 1991), although the

study by Brownlie *et al.* (2000) reported an equal incidence of manic (7/18) and depressive psychosis, with two cases presenting with a schizophreniform psychosis and one with a paranoid psychosis. Other authors have reported that schizophrenic illnesses of various types have sometimes been found to outnumber affective psychoses.

Hyperthyroidism is not associated with a specific type of psychosis, but it is generally considered that a distinctive colouring may be lent by the hyperthyroidism. Thus a manic component may accompany otherwise typical schizophrenic symptomatology, and agitation is often profound in the presence of depression. Most observers are also agreed that paranoid features are especially common whatever form the psychosis may take. The diagnostic distinctions between the affective and schizophrenic reactions are often blurred, and an admixture of organic psychiatric features is relatively common.

Johnson (1928) found only 24 examples of psychosis among over 2000 patients referred for thyroidectomy, when patients with obvious confusion or delirium were excluded. Most were depressive states with hallucinations and delusions. Checkley (1978) was unable to detect a clear time relationship in a careful survey of patients with manic-depressive psychosis who had also had thyrotoxicosis, and argued that if the hyperthyroidism had so little effect on the course of the affective disorder in patients long subject to manic-depressive episodes, it would seem unlikely to serve as a precipitant in patients without such liability. However, Brownlie *et al.* (2000) in a study of 18 patients found a family history of psychiatric illness in only two and a distant past psychiatric history in four. Even after excluding patients with a past psychiatric history, the number of cases of psychosis associated with hyperthyroidism requiring admission was still significantly greater than the 0.36 expected from analysis of community admission data.

Dunlap and Moersch (1935) reported 143 patients with mental disturbance accompanying hyperthyroidism; over 70% were organic psychosyndromes, but 26 patients showed manic-depressive psychoses (mostly depressions), two had dementia praecox and two were paranoid. Bursten (1961) found 10 patients with psychosis among 54 hyperthyroid patients seen in a general hospital during a 4-year period.

Neurological manifestations

A fine low-amplitude tremor at 8–10 Hz that resembles an exaggerated physiological tremor is common. It is most prominent in the small metacarpophalangeal joints in the fingers and in the tongue and eyelids. It is best seen when the arms and fingers are held extended and can be seen both during action and at rest. It appears to be mediated by peripheral β adrenoreceptors (Marsden *et al.* 1970). Chorea and athetosis are rare complications believed to be associated with enhanced striatal dopaminergic sensitivity (Delong

1996). Neuropathy is uncommon and upper motor neurone signs rare, occasionally presenting with muscle wasting and a clinical picture resembling amyotrophic lateral sclerosis (Logothetis 1961). Muscle weakness is common and most prominent in the shoulder girdles, and upper arms and legs. Many patients have clinical signs of myopathy, tendon reflexes are brisk and fasciculations occasionally seen. The well-known signs of lid-lag and upper lid retraction may be accompanied by exophthalmos due to swelling of the retro-orbital tissues.

Generalised seizures are occasionally precipitated by thyrotoxicosis and tend to resolve with treatment of the thyrotoxicosis. EEG changes seen in up to 50% of patients are usually reversible when euthyroidism is achieved (Abend & Tyler 1989). An association between hyperthyroidism and myasthenia gravis is well recognised. Periodic paralysis indistinguishable from familial hypokalaemic periodic paralysis may also occur. Beta-blockers tend to prevent the attacks, which resolve with restoration of normal thyroid function (Conway *et al.* 1974).

Investigations

Laboratory diagnosis of hyperthyroidism is usually straightforward. Most patients have increased unbound thyroxine and tri-iodothyronine and reduced concentrations of TSH. Free or unbound values are measured to avoid difficulties caused by changes in thyroid-binding protein. In 1%, free thyroxine levels are normal with raised free tri-iodothyronine (tri-iodothyronine toxicosis). Failure to suppress TSH in the presence of raised thyroxine raises the possibility of inappropriate thyrotropin syndrome due to a TSH-secreting pituitary tumour or thyroid hormone resistance (Cooper 2003b). In a small number of cases, however, the results may be borderline or even self-contradictory. The clinical features then require careful appraisal, and referral for specialist investigation is usually indicated.

Thyroid function tests have been found to be transiently abnormal in psychiatric patients shortly after admission to hospital. Among 480 newly admitted psychiatric patients, Cohen and Swigar (1979) found abnormalities in total thyroxine, thyroxine-binding capacity and free thyroxine in 9% of the patients, which usually returned to normal within a few weeks. They labelled this 'acute stress hyperthyroidism'. Low thyroxine levels were found in a similar proportion, also often resolving spontaneously.

Differential diagnosis

The differential diagnosis between hyperthyroidism and anxiety neurosis is a classic and often difficult exercise. Presenting symptoms can be virtually identical in both conditions; both show tachycardia, fine finger tremor, palpitations and loss of weight, and both may appear to have been precip-

itated by stressful events. The presence of previous symptomatology of anxiety disorders in thyrotoxic patients can lead to further blurring of the diagnostic criteria between the two conditions.

Careful analysis of the features shown by large numbers of patients with hyperthyroidism has clarified the physical symptoms and signs that are of most importance in indicating this disorder (Wayne 1960). The symptoms, in descending order of discriminating value, are sensitivity to heat and preference for cold, increased appetite, loss of weight, sweating, palpitations, tiredness, 'nervousness' and dyspnoea on effort. In order of importance, the signs are cardiac dysrhythmia (typically atrial fibrillation), hyperkinetic movements, tachycardia exceeding 90 beats per minute, a palpable thyroid gland, a bruit audible over the thyroid, exophthalmos, lid retraction, hot hands, lid-lag and fine finger tremor. These lists show how closely anxiety disorders may be simulated.

Gurney *et al.* (1967) reviewed the features found in euthyroid patients with psychiatric disorder who were initially referred with suspected thyrotoxicosis. Higher frequency of psychological precipitants for the illness, a lower age of onset, more frequent 'hysterical' symptoms and panic attacks, and more neurotic features in the personality were found compared to patients with thyrotoxicosis.

Hyperthyroidism should therefore be strongly suspected when a patient gives a clear history of sensitivity to heat and a preference for cold, and this deserves careful specific enquiry. Similarly, the classical signs of exophthalmos, lid retraction and lid-lag will, when present, give a clear pointer to a diagnosis of hyperthyroidism. Precipitation by stress is found more commonly and impressively in the anxiety disorders. Perhaps the most decisive feature in differentiating the two conditions is the preservation or otherwise of appetite in the face of steady loss of weight; in hyperthyroidism appetite is characteristically increased, whereas in anxiety states it is reduced.

In the presence of frank psychosis, diagnostic difficulties are liable to be increased and the hyperthyroidism may sometimes go unrecognised for a considerable time. It is necessary to beware of the occasional case of hyperthyroidism in which fluctuations occur with periods of spontaneous resolution. Repeated episodes of affective disorder may be particularly misleading:

A man of 40 was admitted to hospital with a typical attack of hypomania that responded satisfactorily to chlorpromazine during the next 3 weeks. Ten days later he was readmitted with a relapse after discontinuing the medication, but once again he responded rapidly to chlorpromazine. Three months later he developed marked weakness and depression, and for the first time appeared to be physically unwell. It was noted that he had a persistent tachycardia, a warm

moist skin and possibly an enlarged thyroid gland. Investigations confirmed hyperthyroidism, and retrospective enquiry revealed steady loss of weight and increased appetite since shortly before the first episode of hypomania. The admission notes on the two previous occasions had shown a tachycardia that had been overlooked at the time.

'Apathetic' hyperthyroidism, presenting with anergia and mental slowing, may cause particular diagnostic difficulty. The typical picture is of a middle-aged or elderly patient with considerable weight loss and apathy or depression (Lahey 1931; Thomas *et al.* 1970). Cardiovascular symptoms may overshadow other evidence of thyrotoxicosis, and eye signs in particular tend to be absent. Depression, particularly agitated, can also be the presenting feature in younger patients. Folks and Petrie (1982) describe a woman of 23 presenting with depression, insomnia and early morning waking, who after an overdose of amitriptyline was found to be thyrotoxic. The affective disorder resolved as the hyperthyroidism came under control. Alcoholism may be wrongly blamed for the tremulousness and emotional lability of hyperthyroid patients (Davis *et al.* 1971).

Aetiology of mental disturbances

The common psychological accompaniments of hyperthyroidism are probably the direct result of increased thyroxine levels and subsequent metabolic derangements within the CNS. This is supported by the uniformity of the common mental changes seen, their fluctuations with exacerbations of the disorder, and their rapid response to antithyroid treatment. In Kathol *et al.*'s (1986) investigation generalised anxiety disorder, but not depression, showed a strong relationship with measures of the free thyroxine index. Cerebral catecholamines may also be intimately involved, particularly increased sensitivity of β -adrenergic receptors. Beta-blocker medications improve psychiatric symptoms in hyperthyroidism despite unaltered levels of thyroid hormones (Trzepacz *et al.* 1988). Similarly, the acute organic reactions are also likely to have an origin in brain metabolic disturbance and usually appear only at peaks of thyrotoxicosis.

The precise aetiology of psychotic developments is incompletely understood. Constitutional predisposition has been suggested to explain severe affective or schizophrenic disorders, although a recent study has suggested that the situation may be complex (Brownlie *et al.* 2000). The psychosis may be precipitated by the metabolic derangement or by the resulting emotional turmoil. Simple coincidence may account for the two developments, but the parallel course which they sometimes pursue suggests that a causal relationship of some sort is likely to exist quite commonly. At all

events, once the processes are under way they doubtless augment one another.

Occasionally, psychoses may develop during treatment with antithyroid drugs (e.g. carbimazole) when thyroid hormone levels are falling. Some are associated with periods of transient hypothyroidism, although others occur when a patient has been rendered euthyroid (Brewer 1969; Herridge & Abey-Wickrama 1969; Bewsher *et al.* 1971; Brownlie *et al.* 2000).

Outcome of mental disturbances

The result of treatment is generally good, with resolution of emotional disorder as the patient is rendered euthyroid. Sometimes, however, emotional instability persists, and in most cases is probably attributable to premorbid tendencies. Kathol *et al.* (1986) found that depression and anxiety resolved in the great majority of cases with antithyroid treatment alone. Occasionally, however, additional psychotropic medication may be necessary. Acute organic and affective psychoses usually also respond rapidly as the thyrotoxicosis comes under control. Schizophrenic psychoses may run a more variable course, but as with other psychoses in which a precipitating cause is apparent the prognosis will usually be better than for schizophrenia that arises spontaneously.

Hyperparathyroidism

Hyperparathyroidism has increasingly gained recognition as a relatively uncommon though important cause of psychiatric morbidity. It is important because, if missed, patients may unnecessarily suffer many years of psychiatric illness that if treated would lead to prompt symptomatic relief. Most cases of primary hyperparathyroidism are due to a solitary adenoma of one of the four parathyroid glands. Hyperfunction in multiple glands (hyperplasia, multiple adenoma and polyclonal hyperfunction) occurs in up to 15%, with less than 1% due to parathyroid carcinoma. A small minority form part of the autosomal dominantly inherited MEN syndrome. MEN type 1, caused by an inactivating mutation of the tumour suppressor *MEN1* gene, is associated with hyperparathyroidism in 85%, endocrine tumours of the pancreas (Zollinger–Ellison syndrome) in 35%, and tumours of the anterior pituitary (prolactinoma) in 25%. MEN type 2a is characterised by hyperparathyroidism in 70%, phaeochromocytomas and medullary carcinoma of the thyroid. It is caused by an autosomal dominantly inherited activating mutation of the *RET* proto-oncogene.

Primary hyperparathyroidism affects women three times as commonly as men. The incidence of primary hyperparathyroidism rises sharply with age, peaking between 55 and 70 years. One study from the Mayo Clinic found a peak incidence of 188.5 per 100 000 in women aged over 60 years (Heath 1980) and it has been claimed that the prevalence in

this group may be as high as 1%. Secondary hyperparathyroidism may result from any cause of hypocalcaemia though is most commonly seen in chronic renal failure due to a combination of hyperphosphataemia and decreased renal production of 1,25-dihydroxyvitamin D.

Physical features

Currently, most patients diagnosed with hyperparathyroidism appear to be asymptomatic (Silverberg *et al.* 1999), although a number of studies have recently suggested that this 'asymptomatic' group may have subtle neurobehavioural symptoms such as fatigue and generalised weakness that resolve after surgery (Burney *et al.* 1999). Prior to the widespread use of multichannel electrolyte analysers renal calculi or diffuse nephrocalcinosis was present in the majority at presentation, though they are now seen in only about 20% (Silverberg *et al.* 1999). Primary hypercalcaemia may also cause cardiac calcification and left ventricular hypertrophy, although there is currently some controversy over whether any of these changes adversely affects life expectancy.

In earlier studies physical complaints were the predominant feature in the great majority, typically presenting with pain, fracture or deformity of bones, renal colic or profound muscular weakness. Occasionally patients present with a myopathic syndrome (Patten & Pages 1984) consisting of proximal muscular weakness, wasting, hypotonia and discomfort on movement. Other common symptoms that may suggest the condition are increased thirst, polyuria, dull diffuse headache, anorexia and nausea. On examination corneal calcification may be seen close to the corneoscleral junction as linear aggregations of granular material.

Psychiatric features

Many of the studies on the psychiatric features of hyperparathyroidism reflect the clinical spectrum seen before the introduction of multichannel electrolyte analysers. In a large series, Petersen (1968) found psychiatric symptoms in two-thirds of patients even after excluding patients who had been referred specifically because of psychiatric disturbance; in one-third the mental abnormalities were severe. Watson (1968) found that a small group presented with mental symptoms alone, whilst Karpati and Frame (1964) identified 4 of 33 patients in whom psychiatric complaints dominated the clinical picture such that they had been referred initially for psychiatric or neurological consultation: a woman of 40 presented with depression that had proved resistant to drugs and psychotherapy for several years before hyperparathyroidism was diagnosed; a woman of 64 had a 2-year history of agitated depression with tremulousness, disorientation, confusion and severe headache; a man of 43 presented with increasing nervousness and obsessive-compulsive features that subsided after operation; and the fourth patient presented with a confusional state accompanied by severe headache.

The commonest mental change in these series was depression with anergia, the patient gradually becoming tired and listless with marked lack of initiative and spontaneity. In Petersen's series, 36% showed these changes, almost all of whom had been unable to work on account of lack of energy during the months preceding operation. Tension and irritability sometimes accompanied the depression, and explosive outbursts were occasionally seen.

In 12% of Petersen's cases organic mental symptoms were present, chiefly impairment of memory or general mental slowing. Acute organic psychoses occurred in 5% of cases, with spells of mental confusion, or acute delirious episodes with hallucinations, paranoia and aggressive behaviour. Stuporose states were also described as were recurrent convulsions leading to coma. Numann *et al.* (1984) showed that even those patients without specific neuropsychiatric complaints at presentation showed significant improvement on tests of verbal memory, verbal reasoning and cognition postoperatively, suggesting that the slow development of these deficits made them less likely to be identified and reported. Very occasionally the degree of intellectual impairment can give rise to a mistaken diagnosis of early-onset dementia.

Psychosis in the absence of an acute psychotic state appears to be rare, and when present is probably coincidental. However, Alarcón and Franceschini (1984) describe a clear example of paranoid psychosis without disorientation or other organic features that resolved after parathyroidectomy and Kleinfeld *et al.* (1984) refer to a case with mania as the sole clinical manifestation.

More recent studies suggest a much milder presentation (Mundy *et al.* 1980), though assessment of apparently 'asymptomatic' patients with mildly elevated parathyroid hormone (PTH) using health status questionnaires such as SCL-90 and SF-36 has shown considerable levels of psychological and functional morbidity that improve rapidly following surgery (Joborn *et al.* 1989; Burney *et al.* 1999). Decreased levels of 5-hydroxyindoleacetic acid (5-HIAA) and homovanillic acid have also been found in the cerebrospinal fluid (CSF) of patients with hyperparathyroidism associated with psychiatric symptoms, reductions that are reversed postoperatively and associated with improved mental functioning at 1 year after surgery (Joborn *et al.* 1988).

Investigations

Most patients with primary hyperparathyroidism have high serum PTH and calcium concentrations. Ionised calcium levels may be more sensitive and should be repeated if clinical suspicion remains despite normal levels. Two-site immunoassays for PTH are now used routinely to detect biologically active forms and minimise cross-reactivity with PTH-related peptide. Serum alkaline phosphatase is raised with bone involvement and renal stones or calcification may be detected on radiography. Hand radiography may occasionally be informative. Computed tomography (CT) of the

brain may show calcification in the caudate nuclei and frontal lobes, although this is very much less common than in hypoparathyroidism since the calcium deposits are usually finely distributed. The EEG shows widespread slow activity, sometimes with paroxysms of frontal delta waves at high serum calcium concentrations.

Differential diagnosis

The disorder should be borne in mind in patients who show chronic affective disorder, anxiety or somatisation in association with suspicious physical symptoms. Symptoms of polydipsia and polyuria or a prolonged, insidiously developing and diagnostically unclear change of personality should trigger assessment of calcium and phosphate, and measurement of calcium and phosphate should be part of the work-up of all patients presenting with acute confusion or fluctuating conscious level.

Aetiology of mental disturbances

The aetiology of the psychiatric disturbance is uncertain, although the elevation of serum calcium appears to play a central role. In his careful review, Petersen (1968) found that the severity of the psychological disturbance appeared to relate to serum calcium levels: affective disorder and disturbances of drive corresponded to a serum calcium of 3–4 mmol/L, acute organic reactions with florid delirium appeared at 4–4.7 mmol/L, and somnolence and coma were found with levels exceeding 4.7 mmol/L. Such a series of changes could sometimes be traced in a single patient. However, subsequent studies have challenged the association between severity of symptoms and serum calcium level, and florid symptoms have been described even in patients with only mildly raised calcium levels (Alarcón 1985). Bleuler (1967) felt that the psychiatric disorders associated with hyperparathyroidism were more constant between patients than those seen with most other endocrine disorders and it has been suggested that this may be because in hyperparathyroidism they depend on a widespread ionic intermediary rather than the direct cerebral effects of a hormone (Lishman 1997). The possible role of hypomagnesaemia remains unclear. The PTH-2 receptor is expressed in various brain regions (Usdin *et al.* 1995), and a brain-specific ligand for this receptor, a hypothalamic neuropeptide, has also been described (Usdin *et al.* 1999), raising the possibility that psychiatric disturbance in hyperparathyroidism may indeed be a direct effect of PTH on the brain.

Outcome

Parathyroidectomy performed by an experienced surgeon is successful in almost 95% of cases and is usually associated with complete resolution of disorders of affect and drive and of the organic psychoses. The time to recovery has been found to be independent of the duration of the disease and of

the severity of the mental changes, and to parallel closely the fall in serum calcium. The rare psychotic states of long duration, with thought disorder and paranoia, may respond less satisfactorily but probably owe a good deal to premorbid vulnerability.

Contemporary presentation with oligosymptomatic or asymptomatic presentation has raised the debate on when patients should be referred for surgery. The natural history of hyperparathyroidism appears to be rather benign. During a 10-year follow-up only 27% of initially asymptomatic patients had evidence of disease progression, defined as the development of one or more new indications for parathyroidectomy (Silverberg *et al.* 1999). However, symptom checklists have shown higher morbidity in 'asymptomatic' patients compared with controls and improvements with surgery, suggesting that truly asymptomatic hyperparathyroidism may be rarer than previously thought.

Hypoparathyroidism

Like hyperparathyroidism, comprehensive reviews of the literature in the 1960s identified hypoparathyroidism as a cause of remediable psychiatric disorder and is now very well recognised. Denko and Kaelbling (1962) identified numerous cases in the literature of patients presenting to varied specialties often over many years and failing to be diagnosed, resulting in the much-delayed institution of treatment that offers an excellent chance of reversing both the physical and psychiatric changes.

Hypoparathyroidism may result from a number of diverse insults to the parathyroid glands. Surgery to the neck, typically for thyroid pathology, may damage the parathyroid glands or disrupt their blood supply, so a history of neck surgery should always be sought in the investigation of suspected hypoparathyroidism. Developmental defects such as DiGeorge's syndrome and the closely related velocardiofacial syndrome, which affect development of the third and fourth branchial arches, result in varying degrees of parathyroid and thyroid hypoplasia. Both syndromes are associated with rearrangement and microdeletions affecting the short arm of chromosome 22. Hypoparathyroidism is also a prominent component of autoimmune polyglandular syndrome type 1, also known as polyendocrinopathy–candidiasis–ectodermal dystrophy syndrome, an autosomal recessively inherited syndrome caused by mutations in the autoimmune regulator gene (*AIRE*) (Björnses *et al.* 2000). Defects in the gene for PTH and in the regulation of PTH secretion (autosomal dominant hypercalciuric hypocalcaemia) have also been described. Occasionally, it may also present in association with Albright's hereditary osteodystrophy. The deficiency of PTH leads to a low serum calcium and a raised serum phosphate. Chronic deficiency may lead to calcium deposits in the skin, lens of the eye and brain.

Fuller Albright described a group of patients who presented with certain developmental and skeletal defects, now

collectively termed Albright's hereditary osteodystrophy, and biochemical abnormalities suggesting end-organ resistance to the actions of PTH. The disorder was subsequently dubbed pseudohypoparathyroidism (PHP) and different forms are classified based on the presence or absence of Albright's hereditary osteodystrophy with or without hormone resistance. The most frequently seen variants include PHP type 1a, pseudo-pseudohypoparathyroidism (PPHP) and PHP type 1b.

- PHP-1a: affected individuals have features of Albright's hereditary osteodystrophy that typically include obesity, short stature, brachydactyly (abnormally shortened bones of the hands and feet, typically affecting the fourth and fifth metacarpals), ectopic calcification and mental retardation. They present with hypocalcaemia with hyperphosphataemia despite elevated serum PTH. Hormone resistance is not usually limited to PTH and individuals frequently show resistance to TSH and gonadotrophins; resistance to growth hormone-releasing hormone and calcitonin has also been described.
- PPHP: affected individuals have the phenotypic features of Albright's hereditary osteodystrophy as described for PHP-1a but do not show evidence of resistance to PTH or other hormones.
- PHP-1b: in contrast to PPHP, affected individuals present with signs and symptoms of PTH resistance but lack features of Albright's hereditary osteodystrophy. Hormone resistance may also be limited to a single tissue, typically the kidney.

The molecular defects responsible for each of the three main forms of PHP appear to reside in the gene encoding the α -subunit of the stimulatory GTP-binding protein ($G_{s\alpha}$). $G_{s\alpha}$ is a ubiquitously expressed signalling protein that mediates the cellular action of numerous hormones and neurotransmitters. Patients with PHP-1a have heterogeneous mutations in one of the $G_{s\alpha}$ exons, leading to reduced protein levels and cellular activity. This suggests that all the hormones affected in PHP-1a act via receptors coupled to $G_{s\alpha}$. Curiously, $G_{s\alpha}$ mutations are also seen in PPHP, where hormone resistance is not seen, and the two disorders are often seen in the same kindred. Interestingly, it has recently been shown that PPHP develops if the $G_{s\alpha}$ mutation is inherited from a male with either PPHP or PHP-1a, whereas PHP-1a results from inheritance of the $G_{s\alpha}$ mutation from a female with either PPHP or PHP-1a. Further, PHP-1b results from a deletion upstream of the $G_{s\alpha}$ gene and is transmitted only from a female, which appears to result in tissue-specific loss of methylation of this gene. A good contemporary review is by Bastepe and Juppner (2003).

Physical features

Hypoparathyroidism should be suspected in patients with symptoms of chronic tetany or when ocular cataracts develop

at an unusually young age. A history of operation on the neck should always raise the possibility of hypoparathyroidism. The continued publication of case reports of untreated hypoparathyroidism and its associated morbidity should serve as a reminder that if it is not considered, symptoms may be endured for many years before diagnosis is made (Bellamy & Kendall-Taylor 1995).

Tetany occurs in the form of numbness and tingling in the hands and feet or around the mouth. With more severe degrees the patient experiences muscular cramps and stiffness in the limbs, carpopedal spasm or laryngeal stridor. In carpopedal spasm, the metacarpophalangeal joints are flexed and the interphalangeal joints of the thumb and fingers are extended to produce a characteristic posture of the hand called *main d'accoucheur*. Epilepsy can be the first and sometimes the only manifestation. In addition to cataracts the patients may have a dry coarse skin, scanty hair, trophic changes in the nails and poor dental development. Calcium deposits may be detected in the skin or appear on skull radiography as calcification in the region of the basal ganglia. Clinically useful signs include twitching of the facial muscles on tapping the facial nerve below the zygoma (Chvostek's sign) and the production of carpopedal spasm by temporarily occluding the circulation to the arm (Trousseau's sign). Very occasionally papilloedema may be observed.

Psychiatric features

Denko and Kaelbling's (1962) literature review served to highlight the high incidence and wide variety of psychiatric disturbances seen in hypoparathyroidism. They estimated that at least half of the cases attributable to surgery had psychiatric symptoms, with an even higher prevalence in hypoparathyroidism with a non-surgical aetiology. The subsequent literature on psychiatric manifestations of hypoparathyroidism is sparse and limited predominantly to case reports and case series.

Denko and Kaelbling classified their 268 cases into five categories: intellectual impairment, organic brain syndrome, psychosis 'functional', pseudoneurosis and undiagnosable. Organic psychiatric syndromes were seen most commonly in the postsurgical group where features of an acute confusional state developed in association with rapid postsurgical biochemical changes. The most common clinical picture in the idiopathic group, which included all non-surgical and non-PHP cases, was intellectual decline. These patients, who had experienced much more insidious and chronic biochemical changes, showed sustained difficulty with concentration, emotional lability and impairment of intellectual functions.

Response to treatment was variable, the majority showing some improvement in overall intellectual function especially if young, though some remained intellectually impaired. Others have shown improvement in concentration, memory,

disorientation and apathy with correction of the hypocalcaemia (Hossain 1970; Illum & Dupont 1985). Kowdley *et al.* (1999) investigated the pattern of cognitive deficits in a case-control study of 11 subjects with chronic hypoparathyroidism treated with calcium and vitamin D supplementation (nine postsurgical, two idiopathic). Some degree of cognitive impairment was seen in seven (65%) of the hypoparathyroid group, of whom two were considered to be severely impaired. Greatest impairment occurred on the Trailmaking B test, forward digit span and oral fluency, which the authors argued was consistent with damage to prefrontal cortex, basal ganglia and thalamus.

'Pseudoneurosis' was described by Denko and Kaelbling as the next most common change in both surgical and idiopathic groups. Children show temper tantrums and night terrors, and adults become depressed, nervous and irritable with frequent crying spells and marked social withdrawal. The emotional disturbances may fluctuate in degree or show periods of spontaneous resolution. Fourman *et al.* (1963) showed that 50% of patients who had undergone thyroidectomy in whom the plasma calcium was merely at the lower limit of normal had mental symptoms in the form of tension and anxiety, panic attacks, depression and lassitude. Often there were no other pointers to parathyroid insufficiency and the symptoms were therefore indistinguishable from those commonly found in what are now classified as anxiety disorders. In a subsequent double-blind trial of calcium citrate tablets and placebo, the authors were able to show a significant improvement in psychiatric symptom scores with treatment (Fourman *et al.* 1967). The most consistent changes were with regard to depression and reduced appetite. Subsequent studies on the clinical efficacy of calcium/vitamin D treatment in chronic hypoparathyroidism are sparse. Though terminating life-threatening hypocalcaemia and debilitating tetanic symptoms, treatment with calcium and vitamin D does not replace the missing hormone, PTH, and may not reverse all the mental symptoms associated with hypoparathyroidism. Arlt *et al.* (2002) found significantly higher global complaint scores on the SCL-90-R, B-L Zersson and GBB-24 in a cross-sectional controlled study of 25 unselected women on standard treatment for postsurgical hypoparathyroidism compared with thyroid surgery controls. Greatest increases were seen in the subtest scores for anxiety, phobic anxiety, somatisation and depression. Twelve of the hypoparathyroidism cases compared with six thyroid surgery controls had severe impairments of well-being, results that remained significant even when those with residual low serum calcium levels were excluded.

More rarely, psychotic illnesses of manic-depressive or schizophrenic type may be seen, particularly in cases due to surgery. Again spontaneous remissions or response to other forms of treatment may delay diagnosis of the underlying condition.

In PHP and PPHP, intellectual impairment is by far the most frequent psychiatric abnormality, occurring in approximately half of reported cases. The prominence of intellectual impairment in PHP and PPHP suggests that it is unlikely to be based solely on the hypocalcaemia (Abrams & Jay 1998).

Investigations

Diagnosis is made on the basis of measurement of serum calcium, magnesium, phosphate and PTH levels. The serum calcium and magnesium are low, serum phosphate is raised, and the urinary excretion of calcium and phosphate reduced. Serum alkaline phosphatase is normal. PTH levels are low except in PHP when they may be normal or raised. Radiological studies show an association between hypoparathyroidism, PHP and basal ganglia calcification. In the study by Frame and Marel (1983), skull radiographs showed calcification in 28% of patients with idiopathic hypoparathyroidism and in 48% of those with PHP. CT studies appear to show a higher prevalence of intracranial calcification in chronic hypoparathyroidism, though caution should be exercised in interpreting these findings in view of publication biases. Illum and Dupont (1985) found calcification in 69% of patients with idiopathic hypoparathyroidism and 100% of those with PHP. Globus pallidus calcification was ubiquitous, caudate nucleus was involved in 14 of 19 cases, and calcification of the putamen, thalamus and cerebral cortex was also commonly seen. EEG abnormalities may be present even in the absence of epilepsy, usually generalised but sometimes surprisingly focal (Watson 1972) (see Table 10.4 and Figure 10.1).

Differential diagnosis

The diagnoses that may be mistakenly entertained include mental retardation, early-onset dementia, anxiety disorders, somatisation disorder, idiopathic epilepsy and cerebral tumour. Diagnosis of an anxiety or somatisation disorder may be suggested by the peculiar and intermittent nature of the symptoms, including bizarre paraesthesiae and muscular spasms. Moreover, the patient may give a vague and perplexing account with obvious difficulty in observing and describing the symptoms. Attacks may be triggered by emotional influences, since hyperventilation will readily lead to tetanic symptoms. Hypochondriasis is readily suggested by the generally heightened level of anxiety, the vagueness of the complaints and the occurrence of periods of spontaneous remission. As a result patients with hypoparathyroidism are sometimes found to have carried a label of psychogenic disorder for several years before the true diagnosis is made. In other cases well-defined mood swings have led to an initial diagnosis of manic-depressive disorder (Denko & Kaelbling 1962).

AD, autosomal dominant; AR, autosomal recessive; MELAS, mitochondrial encephalomyopathy–lactic acidosis–stroke-like symptoms.

Epileptic attacks may be thought to be idiopathic in origin, and the serum calcium should be determined in every epileptic patient when the precise cause of the attacks remains uncertain. Occasionally, increased intracranial pressure and papilloedema are encountered in patients with hypoparathyroidism, this reversing with correction of the serum calcium; cerebral tumour may be closely simulated, especially when fits are present and alteration of personality has occurred.

Outcome

The response to correction of the serum biochemistry is usually gratifying. Anxiety and depressive symptoms are reported to clear in the majority of cases, although recent studies suggest that even with adequate replacement therapy with calcium and vitamin D supplementation and a serum calcium within the normal range these symptoms may be more common than in controls (Arlt *et al.* 2002). Acute confusional states, especially after surgery, resolve rapidly. Ongoing debate surrounds the issue of whether

chronic cognitive impairments resolve with correction of the serum biochemistry. Denko and Kaelbling (1962) noted that when adequate details were given, about half the cases of idiopathic hypoparathyroidism with intellectual impairment improved whereas very few cases were unchanged or worse. Patients with PHP may also improve cognitively when the serum chemistry is corrected, but rarely to a spectacular extent. More recent studies have suggested that even in treated idiopathic and postsurgical hypoparathyroidism intellectual impairment can become chronic and some have suggested that the cognitive impairment is linked to the degree of basal ganglia calcification and to associated motor abnormalities (Kowdley *et al.* 1999). Other complications such as the incidence of cataracts and renal stones appear to increase with chronicity in hypoparathyroidism despite normalisation of serum calcium, suggesting that calcium homeostasis is not normalised with current therapy (Arlt *et al.* 2002). Findings such as these have triggered investigation of the use of more physiological treatments in hypoparathyroidism using subcutaneous PTH or parathyroid allotransplantation.

Fig. 10.1 CT scan of basal ganglia calcification from a patient with mitochondrial encephalomyelopathy with lactic acidosis (MELAS syndrome) showing extensive infarction in both cerebral hemispheres and basal ganglia calcification (caudate, lentiform).

Hypopituitarism (Simmond's disease)

Historically, the commonest cause of hypopituitarism was ischaemic necrosis of the anterior pituitary gland as a result of postpartum haemorrhage (Sheehan's syndrome). Today the commonest cause of panhypopituitarism is pituitary tumours, in particular prolactin-secreting macroadenomas in adults or craniopharyngioma in children. A rare cause of panhypopituitarism is head injury associated with fracture of the base of the skull.

Physical features

The condition is commonly of long duration, sometimes having extended over many years prior to first presentation. Leading symptoms include weakness, ready fatigue and marked sensitivity to cold. There is loss of libido, with amenorrhoea in females and impotence in males. Loss of weight is common, but despite the earlier name of 'pituitary cachexia' is not universal. Nor is it extreme until the terminal stages of the disorder (Sheehan & Summers 1949). In cases with pituitary neoplasms, weight may actually be gained if hypothalamic function is disturbed. Anorexia is common but in some cases appetite is well preserved.

Cardinal signs on examination are a thin dry skin, which fails to tan normally and may become wrinkled as in premature ageing, a flat expressionless face and loss of pubic and axillary hair. The body temperature is often subnormal, the pulse slow with a low blood pressure.

Psychiatric features

The mental picture can be equally striking. The frequency of psychiatric disorder was shown by Kind's (1958) survey of cases from the literature and from his own experience; 90% showed psychiatric symptoms and in half these were severe.

Depression may be marked, sometimes with outbursts of irritability. Drive and initiative are impaired, and the patient comes to spend progressively longer in bed. Virtually all patients show apathy, inertia and somnolence in some degree. Ultimately most are dull and drowsy, prone to self-neglect and indifferent about their state. The degree of psychological change commonly seen is greater than in other chronic debilitating diseases, and the patient's poor physical condition is therefore unlikely to be the complete explanation.

Impairment of memory may occasionally figure prominently and give rise to an impression of a dementing process. Other severe psychiatric complications include episodes of delirium in relation to impending metabolic crises, or more rarely chronic paranoid hallucinatory psychoses.

Metabolic crises may lead on from delirium to hypopituitary stupor or coma, which is always a grave complication. Such severe developments usually set in only several years after the physical disorder has made its first appearance. The following case reported by Blau and Hinton (1960) illustrates the problems that may arise.

A woman of 46 was admitted with drowsiness, neck stiffness and a moderate pyrexia of 2 days' duration. She opened her eyes to her name but would not obey commands and resisted examination. Meningitis was diagnosed at first, but scanty pubic and axillary hair soon led to the diagnosis of Simmond's disease.

Falling blood pressure required intravenous noradrenaline (norepinephrine) in addition to intravenous glucose and hydrocortisone. She emerged from the semicomatose state but remained incontinent and uncooperative and proved to be deluded about her attendants. Violent behaviour necessitated transfer to a psychiatric hospital 2 weeks later, and over the next month she fluctuated from apathy to outbursts of restlessness with aggressive shouting. Memory and orientation were faulty and she was unable to concentrate for long. During the next few weeks she settled into a calm rather foolish euphoria and was correctly orientated for most of the time.

She was followed up with regular treatment with cortisone. Three months after recovery from the coma her mental state and intellectual functions were back to normal. She had recovered her libido, which had deteriorated along with her general health since the birth of her child 10 years previously.

As with Addison's disease, hypopituitarism rarely leads to functional psychoses but commonly to acute organic reactions in association with crises of metabolic disturbance. In both endocrine conditions, alterations of mood form an integral part of the clinical picture and take the form of apathy, anergia and indifference. In all these respects the psychiatric accompaniments and complications are in contrast to those of Cushing's disease, where functional psychoses are common and where the usual mood change is towards depression and emotional lability.

Differential diagnosis

Hypopituitarism must be differentiated from hypothyroidism, in which the facial appearance of the patient is very different, and from Addison's disease, in which pigmentation is a prominent feature. In questionable cases full endocrine assessment is essential before embarking on the appropriate replacement therapy.

From the psychiatric point of view, neurosis and dementia may sometimes be closely simulated, but the principal differential diagnosis is from anorexia nervosa. Many of the early reported cases of hypopituitarism seem in retrospect to have been anorexia nervosa and vice versa (Sheehan & Summers 1949). Now that the situation has been clarified, however, there is rarely clinical doubt, even though both share the cardinal feature of amenorrhoea. Severe weight loss is rare except terminally in hypopituitarism, whereas it is usually a presenting feature in anorexia nervosa. Similarly, appetite may sometimes be well preserved in hypopituitarism. Loss of pubic and axillary hair is unusual in anorexia nervosa, and the fine downy facial hair of anorexia nervosa is rare in hypopituitarism. The psychological features of the two conditions are also very different: in hypopituitarism the patient is dull, apathetic and somnolent, whereas in anorexia nervosa the patient is typically restless and surprisingly active; distinctive attitudes to food and the body image are lacking in hypopituitarism, whereas they form an important constellation of symptoms in anorexia nervosa. When serious doubt exists, full endocrine assessment will clarify the differential diagnosis.

Outcome

Response to replacement therapy is usually good. Within a few days patients experience return of interest and energy, and most lose their symptoms entirely. In cases of very long

duration, however, apathy and lack of drive may persist in some degree. Cortisol or prednisolone alone may suffice, though thyroxine is sometimes given in addition. Gonadal steroids may be required to restore libido and potency in the male.

Hyperprolactinaemia

Hyperprolactinaemia is of importance to psychiatry in two regards: patients with hyperprolactinaemia have been shown to have increased rates of depression, anxiety and hostility, and hyperprolactinaemia is a common and often distressing side effect of the antipsychotic drugs.

Prolactin-secreting adenomas are the commonest secreting tumours of the pituitary. They frequently present with amenorrhoea and more rarely galactorrhoea in women and with impotence and infertility in men. Hyperprolactinaemia is usually due to a microadenoma, a small tumour less than 10 mm in diameter that comprises lactotrophs in the anterior pituitary. Less common are macroadenomas, which may present with headache or visual field disturbance due to focal erosion of the floor of the sella turcica or displacement of the infundibulum and pressure on the optic chiasm. Despite the use of high-resolution CT and magnetic resonance imaging (MRI), there remains a group of patients in whom no pituitary adenoma can be seen. This group may be associated with very small microadenomas undetectable with current imaging or may, as suggested by some investigators, be due to 'functional' hyperprolactinaemia (Sobrinho 1991).

Fava *et al.* (1981) used the Kellner questionnaire and semi-structured interview and identified more symptoms of depression, anxiety and hostility in patients with hyperprolactinaemia compared with amenorrhoeic controls with normal prolactin levels. Keller *et al.* (1985) found hyperprolactinaemic patients to be more depressed and anxious than normals and suggested that these symptoms were worse in those with normal pituitary fossa radiographs compared with those with larger tumours causing erosion of the sella turcica. These symptoms have been shown to improve with dopaminergic agents such as bromocriptine, used in the medical management of hyperprolactinaemia (Buckman & Kellner 1985), although generally they respond poorly to antidepressants. In a review of studies on the psychosomatic aspects of hyperprolactinaemia, Fava *et al.* (1983) suggested that women seem to be more prone to suffer from the behavioural effects of prolactin than males. Reavley *et al.* (1997), in a case-control study of 65 women with hyperprolactinaemia, showed an increased incidence of anxiety, measured with the HAD and SCL-90 scales, in hyperprolactinaemic women compared with a control group with non-functioning pituitary adenomas and normal prolactin levels. Greater psychological distress was found in the group showing no abnormality on CT compared with those with pituitary microadenomas and comparable serum prolactin levels. The authors suggested that these findings supported

the concept of 'functional' hyperprolactinaemia where raised prolactin in the absence of a pituitary adenoma is an endocrine marker of primarily psychological disturbance.

In a number of recent reviews, Wieck and Haddad have drawn attention to the chronic effects of iatrogenic hyperprolactinaemia, a common side effect of antipsychotic use (Wieck & Haddad 2002; Haddad & Wieck 2004). Hypothalamic dopamine is the predominant inhibitor of prolactin release, an action mediated via binding to D₂ receptors on the surface of pituitary lactotrophs. All conventional antipsychotics and some of the atypical ones, notably risperidone and amisulpride, block D₂ receptors on lactotrophs, removing the inhibitory influence of dopamine and causing a marked and sustained increase in serum prolactin levels. In addition to the effects highlighted above, hyperprolactinaemia has adverse effects on sexual function, the breasts and, via secondary hypo-estrogenism, bone mineral density. It may lead to breast enlargement and galactorrhoea, ovarian dysfunction, infertility, reduced libido, atrophic changes in the urethra and vaginal mucosa, reduced vaginal lubrication and dyspareunia. Acne and mild hirsutism may also develop and the loss of the protective effect of estrogens on bone resorption can lead to reduced bone mineral density. Two small studies have suggested an association between chronic antipsychotic medication and reduced bone mineral density (Ataya *et al.* 1988; Halbreich *et al.* 1995). Although these findings are only preliminary and both studies suffered from a number of methodological difficulties, they suggest that the consequences of chronic hyperprolactinaemia on the skeleton secondary to antipsychotic use need to be carefully considered.

Acromegaly

Acromegaly results from overproduction of growth hormone, usually from a pituitary somatotroph adenoma though rarely from simple hyperplasia of the eosinophil cells of the anterior pituitary gland. The actions of growth hormone are effected via insulin-like growth factor (IGF)-1, a peptide with endocrine, paracrine and autocrine actions generated in many tissues. It is also responsible for the clinical features seen in acromegaly. Skeletal overgrowth develops insidiously, leading to increased hand, foot and hat size, prognathism, enlarged tongue, wide spacing of the teeth and coarsening of the facial features. Most patients also complain of neurological and musculoskeletal symptoms such as headaches, nerve entrapments, muscle weakness and joint pain. Insulin resistance occurs in the majority though clinical diabetes mellitus is seen in only 20%. Obstructive sleep apnoea, hypertension and hypogonadism are seen frequently. Life expectancy is considerably shortened, with increased rates of death from cardiovascular, cerebrovascular and respiratory disease.

The literature on psychological and psychiatric accompaniments remains sparse. The first case series was performed

by Bleuler (1951) on 22 patients seen at the Burghoelzli Clinic, Zurich and an additional six cases from the clinic of the New York Hospital. He described alterations of personality, mainly a lack of initiative and spontaneity, sometimes interrupted by brief periods of impulsive behaviour and changes of mood ('frequent cheerfulness, self-satisfaction and elation occur with passivity and indifference') and regarded brief periods of moodiness with frequent mood swings as characteristic. Bradyphrenia was observed in the late stages though no intellectual impairment was seen. Social attitudes were characterised by egocentricity and lack of consideration and interest in others, leading to problems with other members of the family and at work. In contrast to earlier reports he found no evidence for an increased incidence of schizophrenic or mood-related psychosis, arguing that the previously reported association was likely due to publication bias.

Few subsequent systematic studies have sought to follow up these impressions. Anecdotal reports have emphasised depression and anxiety and loss of impulse control, coupled with loss of self-confidence and concern over body size (Avery 1973). Margo (1981) reported a patient with a chronic depressive illness with prominent psychomotor retardation beginning 12 years before the acromegaly was diagnosed. Sivakumar and Williams (1991) described a patient with insidious-onset depression and marked behavioural change characterised by pathological gambling out of keeping with his premorbid personality. However, repeated neuropsychometry including tests of frontal lobe functioning failed to show any associated cognitive impairment. Spence (1995) also described apparent loss of impulse control in a woman who presented with psychotic depression and sudden onset of impulsive shoplifting prior to diagnosis of acromegaly 3 years later.

It is hard in such examples to know how far simple coincidence or publication bias may be responsible. Abed *et al.* (1987) used standardised assessments (GHQ and Present State Examination) and failed to find any general increase in psychiatric morbidity, nor a specific increase in depression when compared with rates in other population studies in a survey of 51 acromegalic patients. Indeed, the scores were significantly lower than in certain other samples, and the interviewer was impressed with the optimism and even elation shown by many of the subjects. No overall relationship could be found between growth hormone levels and psychiatric morbidity; however, females showed significantly higher morbidity rates than males, and 10 of the 11 subjects who scored above the cut-off points for psychiatric illness were women. However, the instruments used in this study were unsuited to the measurement of personality change and formal neuropsychometry was not performed so these aspects remain to be elucidated. Historically, a number of reports have described patients as sometimes reserved, touchy and irritable, with emotional lability, and traits of obstinacy and impulsivity. How far such features may be understandable as reactions to disfigurement, headache and

limb pain or whether they depend on metabolic changes or basal brain compression has not been clarified.

Neurological complications include mild proximal myopathy, carpal tunnel syndrome and visual field defects. Carpal tunnel syndrome has been reported in up to 64% at presentation, showing a significant improvement when circulating growth hormone levels are reduced (Baum *et al.* 1986). Using MRI, Jenkins *et al.* (2000) found oedema of the median nerve rather than a change in the volume of the contents of the carpal tunnel, as seen in idiopathic carpal tunnel syndrome, and went on to argue that appropriate management is therefore aggressive treatment of the underlying pituitary hypersecretion rather than surgical decompression. Recent studies on the association of visual field defects with acromegaly suggest that they are now less commonly seen. Studies from the 1970s suggested that they were present in up to 90% of all pituitary tumours, whereas contemporary studies suggest that this is now approximately 20% (Rivoal *et al.* 2000). Hypersomnia may be a consequence of sleep apnoea occasioned by airway obstruction due to macroglossia and hypertrophy of the pharyngeal soft tissues (Perks *et al.* 1980; Seggev *et al.* 1986). In some cases, however, the daytime somnolence remits rapidly on treatment of the acromegaly, suggesting that it is not solely due to airway obstruction.

Trans-sphenoidal removal of the responsible pituitary adenoma is the treatment of choice for most patients (Paisley & Trainer 2003). However, the presence of macroadenomas in 70% often means that tumour removal is incomplete, necessitating additional medical therapy and/or radiotherapy. Previously, dopamine agonists such as bromocriptine and cabergoline that inhibit growth hormone were the mainstay of treatment. Whilst associated with symptomatic relief in the majority of patients, they led to a normalisation of growth hormone and IGF-1 in only about 35% and were associated with a number of unpleasant side effects including headache and mood disturbance. There have also been a number of case reports of their association with schizophreniform or manic-like psychoses (Le Feuvre *et al.* 1982; Turner 1984; Boyd 1995). Long-acting somatostatin analogues such as octreotide and lanreotide, which inhibit growth hormone secretion via somatostatin receptor subtypes 2 and 5 expressed on adenomas, can induce tumour shrinkage and have been associated with a normalisation of growth hormone/IGF-1 in up to 65% of individuals (Paisley & Trainer 2003). A recently developed growth hormone receptor antagonist, pegvisomant, has been shown to achieve superior biochemical disease control in two controlled trials and has recently been licensed in the European Union.

Diabetes insipidus

Diabetes insipidus is a syndrome of polyuria with secondary polydipsia and comprises two types: inadequate production of circulating antidiuretic hormone (ADH, vasopressin) is

the cause of central diabetes insipidus, whereas a lack of ADH action on the kidney causes nephrogenic diabetes insipidus. ADH is synthesised in the supraoptic and paraventricular nuclei of the hypothalamus and then transported to the posterior pituitary from where it is released into the circulation. ADH binds to V_2 receptors on the nephron collecting tubules, stimulating adenylate cyclase and ultimately the insertion of aquaporin water channels, which result in increased water reabsorption and the consequent production of a more concentrated urine.

Central diabetes insipidus develops when insufficient ADH is produced by the posterior pituitary. Causes include hypothalamic tumours, traumatic head injury, infiltration (e.g. sarcoidosis), infection (e.g. tuberculosis) and trans-sphenoidal surgery; 10–30% of cases are idiopathic. Occasionally, the condition is familial, inherited as an autosomal dominant condition due to mutations in the ADH signal peptide or in the neurophysins. It may present abruptly at any age without apparent cause, usually as an isolated abnormality but occasionally with other indications of hypothalamic disorder.

Nephrogenic diabetes insipidus is caused by a failure of the renal tubules to respond normally to ADH. Causes in adults include hypercalcaemia, potassium depletion and the prolonged intake of excessive amounts of water, all of which can impair the action of ADH on the nephron. A variety of drugs, including lithium, may also be responsible. Polyuria from lithium treatment can develop when plasma levels are within the therapeutic range; 40% of patients on lithium experience thirst, with perhaps 12% developing polyuria (Ledingham 1983). In most cases this resolves within several weeks of withdrawing the drug. It may also occur as a rare sex-linked recessive disorder affecting males, due to defects in the ADH receptor gene or less frequently as an autosomal recessive, due to defects in the vasopressin-sensitive aquaporin 2 channel.

Both central and nephrogenic diabetes insipidus result in the production of large volumes of dilute urine, normally accompanied by thirst. Urine osmolality is low, but plasma osmolality is usually only slightly raised provided the thirst mechanisms are intact and the patient drinks adequately. If thirst does not occur, or if fluid intake is prevented, a dangerous degree of hypernatraemia and dehydration may develop. The differential diagnosis of diabetes insipidus includes primary renal disease, diabetes mellitus, polydipsias induced by drugs such as chlorpromazine or thioridazine (which may stimulate drinking by a direct action on the hypothalamus) and primary or psychogenic polydipsia.

The treatment of choice for neurogenic diabetes insipidus is the synthetic ADH analogue desmopressin (1-deamino-8-D-arginine vasopressin, DDAVP). It has a long duration of action and may be given once or twice daily orally, by nasal spray or subcutaneously. Nephrogenic diabetes insipidus is more difficult to treat. Most are treated with thiazide

diuretics to cause volume contraction and reduce glomerular filtration rate.

Primary polydipsia (psychogenic polydipsia)

Primary polydipsia may be associated with a wide range of psychopathology: psychosis, mood disorders and personality disorder. In psychotic patients it is frequently delusionally motivated. Barlow and De Wardener (1959) described nine cases in whom long-standing personality disorder was common, often with hypochondriasis and depression. Six had experienced episodes of conversion disorder and some had histories of compulsive eating. Denial and evasion were sometimes a prominent part of the picture. Mercier-Guidez and Loas (2000), in a study of all psychiatric inpatients in a defined geographical area, estimated that polydipsia and polyuria occur in 11% of all psychiatric inpatients, especially those with chronic schizophrenia.

Primary polydipsia may simulate diabetes insipidus closely. In both conditions the fluid intake and output are raised and urine osmolality is low. In primary polydipsia, however, plasma osmolality is also likely to be low and hyponatraemia may develop when water intake is so excessive that it exceeds the kidneys' ability to excrete it. Onset may be clearly related to a depressive phase or period of stress, or other evidence of psychiatric disorder may be present. The onset will often be gradual rather than abrupt, and consumption may tend to fluctuate from hour to hour or day to day in contrast to the steadily increased intake of diabetes insipidus. Nocturia is uncommon compared with diabetes insipidus when it is commonly seen (Table 10.5).

Distinguishing primary polydipsia from diabetes insipidus

Not infrequently, however, the distinction can be difficult despite water deprivation testing. In normal subjects fluid deprivation over an 8-hour period leaves plasma osmolality unchanged, while urine osmolality rises to twice that of the plasma. In diabetes insipidus the plasma osmolality rises but that of the urine remains relatively low. In primary polydipsia both the initial plasma and urine osmolality are low, and plasma osmolality rises to normal at the end of the test.

However, urine osmolality may fail to rise to twice that of the plasma because the prolonged excessive water intake may have led to a secondary nephrogenic diabetes insipidus. Prolonged water deprivation (carefully monitored) for 2–4 days may be necessary to allow the return of normal renal function, or this may be even longer delayed.

When compulsive water drinking is mistaken for diabetes insipidus and treated with ADH, hyponatraemia and symptoms of water intoxication can develop (see Hyponatraemia, later). Water intoxication also seems to be a special hazard in compulsive water drinking associated with psychosis; numerous examples of such a complication have been described in patients with schizophrenia, sometimes presenting acutely with vomiting, impairment of consciousness or fits (Jose *et al.* 1979; Khamnei 1984; Singh *et al.* 1985; Grainger 1992). Fatalities have been reported from time to time (Vieweg *et al.* 1985).

Both Jose *et al.* (1979) and Khamnei (1984) noted that a high proportion of patients with water intoxication secondary to polydipsia were psychotic, sometimes with evidence of the syndrome of inappropriate ADH secretion (SIADH). In other cases there have been indications of enhanced renal sensitivity to vasopressin (Goldman *et al.* 1988; Emsley *et al.* 1989). However, how far such features may reflect hypothalamic or other disorders intrinsic to the psychosis is uncertain. Multiple factors may often be at work, including the effects of medical illnesses or drugs (Fowler *et al.* 1977; Illowsky & Kirch 1988).

Many psychotropic medications, including all antidepressants, phenothiazines, haloperidol, thiothixine, carbamazepine and tranylcypromine, can precipitate SIADH (Sandifer 1983; Grainger 1992). In half of the cases reviewed by Sandifer, hyponatraemia, usually in association with SIADH, had developed within a week of starting medication. When hyponatraemia is found in a patient taking psychotropic medication it is important to test the response to a water load while on and off the drug, after ensuring that the serum sodium has been restored to normal.

It is important to enquire for a history of polydipsia in any psychotic patient who presents with seizures or lowering of consciousness. Similarly, the discovery of polyuria with a low urinary specific gravity should always lead to careful observation of the patient's water intake. This may on

Table 10.5 Differentiation of primary polydipsia and diabetes insipidus. (From Asbury & McKhann 2002.)

Feature	Primary polydipsia	Diabetes insipidus
Onset of polyuria	Gradual	Sudden
Nocturia	Unusual	Common
Random plasma osmolality	Sometimes <28.5 mosmol/L	Normal or elevated
Morning plasma osmolality	Normal	Elevated
Morning urine osmolality	Normal	Inappropriately low
Plasma ADH concentration	Normal relative to plasma osmolality	Low relative to plasma osmolality (in neurogenic diabetes insipidus)

occasion be skilfully concealed. Treatment must aim at restricting fluid intake, along with attempts to obtain maximal control of the patient's psychiatric disorder. Where long-term fluid restriction proves to be impractical or when an offending medication must be continued, demeclocycline may be useful in normalising serum sodium by inhibiting the action of ADH on the kidneys (Illowsky & Kirch 1988).

Cushing's syndrome

Cushing's syndrome is caused by chronic excess of glucocorticoids and has a number of different aetiologies. The most common form, accounting for 60–80% of cases in most series, is a pituitary adenoma producing excess corticotrophin (ACTH). This results in secondary bilateral hyperplasia of the adrenal cortices and is known as Cushing's disease (Mampalam *et al.* 1988). Typically, these pituitary tumours are microadenomas (<1 cm in diameter) and are rarely large enough to cause chiasmatic compression or raised intracranial pressure. Cushing's syndrome may also be caused by ectopic ACTH secretion (e.g. by small-cell lung carcinoma) or by ACTH-independent mechanisms, with excess cortisol production resulting from unilateral adrenocortical tumours, either benign or malignant, or by bilateral adrenal hyperplasia or dysplasia (Boscaro *et al.* 2001). Iatrogenic and factitious Cushing's syndrome may occasionally be associated with exogenous administration of ACTH, though is more commonly seen with long-term treatment with glucocorticoids such as prednisolone or dexamethasone.

Apart from differing levels of circulating ACTH, the endocrine abnormalities are the same whether due to adrenal or pituitary disease: a sustained excessive production of cortisol that obliterates the normal diurnal rhythm, and usually excessive production of adrenal androgens as well. Alcohol dependency may also produce clinical features identical to those seen in Cushing's syndrome in a minority of susceptible individuals. The clinical picture may be accompanied by abnormalities of cortisol secretion and in particular a loss of circadian rhythm. The mechanism through which alcohol interferes with cortisol secretion is unclear, although it has been suggested that it interferes with steroidogenic pathways by decreasing 11 β -hydroxysteroid dehydrogenase activity (Groote Veldman *et al.* 1996). The clinical and hormonal features typically resolve within days or weeks when the alcohol intake stops and this is the simplest way of avoiding a false diagnosis (Smals *et al.* 1976; Morgan 1982; Boscaro *et al.* 2000).

Cushing's syndrome is rare: the annual incidence of Cushing's disease is 0.1–1.0 per 100 000 and is three to eight times more common in women than in men (Boscaro *et al.* 2001). Incidence peaks in women between the ages of 25 and 50 years though the range of ages at onset is wide. A tendency has also been noted for the disorder to start during pregnancy, at the menopause or at puberty, or while the subject is

undergoing a prolonged period of psychological stress, with repeated studies showing an association between onset of the hypothalamic–pituitary form of Cushing's disease and stressful life events (Sonino *et al.* 1993a).

The great majority of cases present for medical attention on account of the physical disorder that develops, but psychiatric features are strikingly frequent and can be severe. Moreover, occasional cases have been reported to present with psychiatric illnesses from the outset, as discussed below, and the endocrine disorder may then be recognised only after a considerable delay.

Physical features

The physical changes most commonly seen in Cushing's syndrome are shown in Table 10.6, together with their relative frequencies in one series. However, it should be noted that the occurrence of any single feature varies so widely between series that no single finding is necessary for diagnosis. Truncal obesity is almost always present and associated with supraclavicular fat accumulation, a cervical fat pad (the well-known 'buffalo hump'), facial fullness (the moon face) and purple striae produced by rapid expansion of the trunk and abdomen. The complexion is plethoric and hirsutism may be marked. Excessive bruising or extensive ecchymoses and atrophy of the skin may also be seen. Skin pigmentation may develop from the direct action of excessive ACTH on melanocytes. Hypertension is often severe and glucose intolerance or frank diabetes mellitus may also develop. Amenorrhoea is usual in women, and impotence, testicular atrophy or gynaecomastia commonly seen in men. Other important features include proximal muscle weakness and associated muscle wasting, a liability to intercurrent infections, especially fungal, and osteoporosis leading to backache or

Table 10.6 Frequency of physical signs and symptoms in a group of 302 individuals with Cushing's syndrome. (From Boscaro *et al.* 2001.)

Sign/symptom	Frequency (%)
Truncal obesity	96
Facial fullness	82
Diabetes or glucose intolerance	80
Gonadal dysfunction	74
Hirsutism, acne	72
Hypertension	68
Muscle weakness	64
Skin atrophy and bruising	62
Osteoporosis	38
Oedema	18
Polydipsia/polyuria	10
Fungal infections	6

The mean age of the 302 patients (239 female and 63 male) was 38.4 years (SD 13.5 years, range 8–75 years).

vertebral collapse. However, the clinical phenotype is not always florid and suspicion should always arise with a less complete picture especially if there is concomitant recent weight gain, impaired glucose tolerance and high blood pressure (Arnaldi *et al.* 2003).

Psychiatric features

In an early series of 25 consecutive patients seen in a general hospital, Trethowan and Cobb (1952) showed that psychiatric disturbance is common and reflects the findings in more recent studies. Of their patients, four were described as severely disturbed and psychotic, six as moderately disturbed and eight mildly disturbed; three had relatively insignificant psychiatric symptoms but only four could be declared mentally normal. Jeffcoate *et al.* (1979) surveyed 40 patients of whom 22 were depressed, five severely, and four showed other psychiatric disorders (mania, chronic anxiety and an acute organic reaction). Only one-third was judged to be free from mental disorder. Whybrow and Hurwitz's (1976) literature review supported these findings and suggested that less than 4% showed euphoria, in contrast to the situation when exogenous steroids are administered for therapeutic purposes. Later prospective studies such as that by Starkman *et al.* (1981) have reported an even higher frequency of psychiatric symptoms (Table 10.7). Irritability was the earliest symptom in most cases, often antedating the physical manifestations. Patients described themselves as having become oversensitive and unable to ignore minor irritations. Verbal dyscontrol was frequent, patients noting that they were overly argumentative and unable to 'hold their tongue'. Depressed mood was reported in three-quarters. It was often of sudden onset and was usually intermittent rather than sustained, rarely lasting for longer than 3 days at a time. Social withdrawal when present was related to feelings of discomfort in large groups and seemingly due to feelings of shame at their physical appearance.

Depression is widely reported as one of the most frequent psychiatric symptoms and is often seen with paranoid features. Cohen's (1980) study was important as it reported a consecutive and unselected series of 29 patients with Cushing's syndrome examined closely from the psychiatric point of view; 25 (86%) showed a significant degree of depression, this being mild in seven, moderate in 13 and severe in five. The author also found that almost half of the series had a family history of depression or suicide, or a past history of early bereavement or separation, and six had experienced a major emotional disturbance shortly preceding the onset of the endocrine disorder. These are all factors of known importance in the genesis of depression and raised the possibility of an aetiological link between Cushing's syndrome and depressive illness. Moreover, depression was particularly common among the 21 patients with a pituitary origin for

Table 10.7 Frequency of psychiatric symptoms in a group of 35 individuals with Cushing's syndrome. (From Starkman *et al.* 1981.)

Symptom	Frequency (%)
Increased fatigue	100
Decreased energy	97
Irritability	86
Impaired memory	83
Depressed mood	74
Decreased libido	69
Middle insomnia	69
Anxiety	66

Paranoid thoughts	9
Hyperactivity	9
Depersonalisation	3
Persistent anhedonia	3
Derealisation	3
Decreased fatigue	3
Increased energy	3

their Cushing's syndrome, and all six patients with a disturbing life event preceding it fell into this group.

More recent studies using standardised diagnostic criteria have found major depression meeting DSM criteria in 57–80% (Haskett 1985; Kelly 1996), with no significant differences in the prevalence of depression between patients with pituitary-dependent and -independent forms (Sonino *et al.* 1993b; Kelly 1996). However, the presence of major depression has been associated with older age, female gender, higher pretreatment cortisol levels and a more severe clinical condition (Sonino *et al.* 1998). Acute anxiety may also figure prominently, with one small study (Loosen *et al.* 1992) showing that 79% of the subjects with Cushing's disease fulfilled DSM-III-R criteria for generalised anxiety disorder. Apathy verging on stupor may be seen and fatigue and asthenia derived from the physical disorder often colours the psychiatric picture.

The psychoses accompanying Cushing's syndrome are mostly depressive in nature. When they occur they are typically florid illnesses with delusions and auditory hallucinations, often with paranoid symptoms. Retardation may be severe, sometimes bordering on stupor. Anxious agitation may replace the retardation in other cases, or there may be acute brief episodes of grossly disturbed behaviour. Marked fluctuations in the severity of the condition appear to be characteristic. Most recent studies using standardised diagnostic criteria have failed to identify any cases of schizophrenia or acute confusional states (Kelly 1996) or found them only in conjunction with particularly high cortisol and ACTH levels (Starkman *et al.* 1981). However, case reports occasionally appear in the literature and may reflect a tendency to publish unusual patients (Johnson 1975).

There has been considerable interest in defining the cognitive changes associated with Cushing's syndrome and more broadly in conditions associated with excess glucocorticoids. Typically, patients with Cushing's syndrome complain of difficulties with concentration and memory. In her study on 48 subjects with untreated Cushing's disease, Starkman (2001) showed significantly lower scores on four of five verbal IQ subtests but on only one non-verbal subtest in patients with Cushing's disease compared with healthy controls. Verbal but not visual learning and delayed recall at 30 minutes were also significantly decreased in the Cushing's disease group. This selective impairment in verbal compared with visuospatial learning appeared to be a result of impaired initial learning rather than retention or retrieval. There was no significant association between severity of depression and cognitive performance, suggesting that the behavioural domains of mood and cognition may be affected independently of each other in response to hypercortisolaemia. A similar pattern of cognitive impairment is also described in post-traumatic stress disorder (Bremner *et al.* 1995) that is associated with raised cortisol levels and in subjects who have received several days of stress-level exposure to corticosteroids (Newcomer *et al.* 1999).

Aetiology of mental disturbances

The depression so characteristic of Cushing's syndrome is doubtless partly a reaction to the physical disfigurements and discomforts produced by the disease. But a more direct connection is suggested in those cases where affective disorder is an early or even presenting feature, and by the frequency with which the depression reaches 'psychotic' intensity.

Cohen's (1980) observations are particularly interesting in this regard. The common finding of factors predisposing to depression in the histories of his patients may merely illustrate their vulnerability to depression in the face of physical illness; on the other hand, it may indicate something more – a

close pathophysiological link between the genesis of depression and the genesis of some forms of Cushing's syndrome. Thus it is noteworthy in his series that depression was significantly more common in primary pituitary than primary adrenal forms of the syndrome, a difference that had already been discerned by Carroll (1976) from cases in the literature. Disturbing life events, antecedent to the development of the endocrine disorder, were confined to this form of the disease. However, more discriminating controlled studies will be necessary before concluding that Cushing's syndrome may sometimes be induced by stress.

The depression of Cushing's syndrome has often been contrasted with the elevation of mood characteristically seen when steroids or ACTH are administered for therapeutic purposes. Whether the difference is due to differing plasma levels of biologically active steroids or to the long-continued chronic elevation of steroids in Cushing's syndrome is not known. Neither Cohen (1980) nor Kelly *et al.* (1983) could relate the severity of depression to the levels of circulating cortisol in their patients, yet its alleviation after surgical removal of the hyperplastic adrenal glands suggests that it must owe a good deal to some substance they produce. Hypothalamic factors may also be presumed to play a part in view of the complex neuroendocrine relationships now apparent in the control and regulation of the hypothalamic–pituitary axis. In cases of pituitary origin, additional factors could be the increased levels of β -endorphin and methionine-enkephalin that are secreted along with ACTH (Fava *et al.* 1987).

The discovery of glucocorticoid and mineralocorticoid receptors in the brain (McEwen *et al.* 1986) has stimulated interest in the pathophysiological mechanisms by which cortisol may affect cognitive and emotional functioning. Animal studies have shown that the hippocampi are especially vulnerable to excess or deficit of glucocorticoids and exposure to exogenous corticosteroids induces changes in hippocampal pyramidal cell morphology and pyramidal cell loss (Sapolsky *et al.* 1990). Prolonged exposure to high levels of glucocorticoids is associated with impaired long-term potentiation (Kerr *et al.* 1991) and impairs memory performance. Starkman *et al.* (1992) and subsequently others (Bourdeau *et al.* 2002) have shown variability in hippocampal formation volume in Cushing's syndrome on MRI, with 27% of subjects having a hippocampal volume outside the 95% confidence interval for the normal hippocampal volume quoted in the literature, the reduction in volume of the hippocampal formation correlating significantly with measures of verbal memory impairment and negatively with the levels of plasma cortisol. The hippocampal formation contains the highest proportion of corticosteroid-binding sites in the brain, particularly in the CA1, CA3 and dentate regions, which may make it particularly vulnerable in Cushing's disease. It should be noted, however, that normal hippocampal volumes quoted

in the literature show fourfold variation (Colchester *et al.* 2001), so there is not yet an unequivocal reference standard.

Recent studies by Starkman *et al.* (1999) and Bourdeau *et al.* (2002, 2005) suggest that the hippocampal and general cerebral atrophy reported in Cushing's syndrome may be partially or even fully reversible following successful treatment of the underlying endocrinopathy. Furthermore, there is some evidence to suggest that this improvement in hippocampal and possibly general cerebral volume is associated with an improvement in function, particularly in learning (Starkman *et al.* 2003). In their study of 22 patients treated surgically for Cushing's disease, Starkman *et al.* showed a mean increase in hippocampal volume of $3.2 \pm 2.5\%$ at a mean of 16 months after surgery. The percentage increase in hippocampal volume significantly correlated with the magnitude of the change in urinary free cortisol levels. Bourdeau *et al.* used third ventricle diameter and bicaudate diameters as surrogate measures of cerebral atrophy and showed highly significant improvements in both in 38 patients with Cushing's syndrome treated surgically at an average of 40 months' follow-up. The mechanism for this apparent increase in cerebral volume is currently unclear. It is interesting to speculate that this may be the result of increased pyramidal cell dendritic branching or the production of new hippocampal neurones, a consequence of granule cell neurogenesis in the dentate gyrus resulting from reduced cortisol suppression. Eriksson *et al.* (1998) have also demonstrated production of new hippocampal neurones in human brain though, as cautioned by Starkman, these apparent increases in volume may simply be the result of an increase in the water content of grey and white matter resulting from the reduction in cortisol levels. In this regard it should be noted that corticosteroids are frequently used and often effective in reducing cerebral oedema associated with intracranial tumours.

Outcome

A successful psychiatric outcome can be expected when the endocrine disorder is effectively treated. The physical and mental symptoms usually improve in parallel until the patient regains his former stability. Depression is regularly observed to recede after adrenalectomy, pituitary operation or treatment with metyrapone, often starting to abate within days or weeks though sometimes taking as long as a year to clear completely (Jeffcoate *et al.* 1979; Cohen 1980; Kelly *et al.* 1983). Needless to say, when psychiatric disturbance has long antedated the Cushing's syndrome, there may be little or no change when the latter is remedied.

With florid psychotic illnesses the results can be dramatic, as in the following case vignettes.

For details of the medical management of the condition readers should consult a textbook of medicine.

A woman presented initially with physical symptoms of Cushing's syndrome, but on admission to hospital developed an acute psychotic picture with auditory and visual hallucinations and delusions about changing her sex. This was thought to have been precipitated partly by the mounting anxiety surrounding her admission to hospital. She became markedly paranoid and agitated, developed confusional episodes and showed bizarre catatonic motor phenomena. The entire condition responded well to bilateral extirpation of the hyperplastic adrenal glands and her mental state returned to normal within a few days of the operation. Follow-up 3 years later showed that she remained entirely well (Hickman *et al.* 1961).

A soldier of 23 with a good service record became abruptly confused and hallucinated, and showed severely disturbed behaviour with grandiose and religious delusions. He was diagnosed as schizophrenic and treated extensively with electroconvulsive therapy. It was not until 1 year later that Cushing's syndrome was diagnosed. He continued to be severely disturbed, but pituitary irradiation 18 months and 2 years after onset led to transitory amelioration of the psychotic symptoms. Two and a half years after onset bilateral adrenalectomy was performed, and thereafter there was steady and gradual improvement until full premorbid stability was regained (Hertz *et al.* 1955).

Addison's disease

Primary adrenal insufficiency or Addison's disease results in a deficiency of all adrenal steroids: glucocorticoids, mineralocorticoids and adrenally produced androgens. It has a prevalence of 93–140 per million (Arlt & Allolio 2003) and affects women more commonly than men. Peak onset is in the fourth decade. In developed countries the most common cause is autoimmune destruction of the adrenal glands. Autoantibodies seen in the disorder appear to be directed against the 21-hydroxylase enzyme, involved in steroidogenesis, and other endogenous adrenal cell antigens (Winqvist 1992).

Addison's disease with an autoimmune aetiology (60% of cases) occurs as part of the autoimmune polyglandular syndrome (APS), whereas in the remaining 40% of cases the disease occurs alone. APS type I is a childhood disease characterised by chronic mucocutaneous candidiasis, hypoparathyroidism, primary adrenal insufficiency and, in a minority, childhood alopecia, chronic active hepatitis and malabsorption. It is caused by mutations in the autoimmune regulator gene (*AIRE*) and is inherited in an autosomal recessive manner (Nagamine *et al.* 1997). APS type II, or Schmidt's syndrome, is a disease of adults and comprises

adrenal insufficiency, hypothyroidism, primary gonadal failure and type 1 diabetes; vitiligo, chronic atrophic gastritis or celiac disease may also occasionally be seen. It is inherited as an autosomal dominant disorder with incomplete penetrance.

Tuberculous infiltration is the second most common cause of Addison's disease in developed countries and the most common cause in developing countries. Secondary adrenal insufficiency may result from suppression of the hypothalamic-pituitary-adrenal axis, typically following chronic administration of glucocorticoids though rarely may also be due to local hypothalamic or pituitary lesions. It too is seen more commonly in women than men and has a peak incidence in the sixth decade, later than that seen in primary adrenal insufficiency (Nilsson *et al.* 2000).

Physical features

The onset of symptoms is gradual and the usual presentation is with general weakness, lack of stamina and fatigue. Chronic glucocorticoid deficiency leads to weight loss, nausea and anorexia and may account for muscle, joint and abdominal pain. Orthostatic hypotension with postural dizziness is seen in 90%, and may be seen in association with salt craving resulting from mineralocorticoid deficiency. Loss of dehydroepiandrosterone (DHEA), the major precursor of the adrenally produced sex steroids, can lead to loss of libido, dry skin and loss of axillary and pubic hair and is seen predominantly in women. On examination most have hyperpigmentation in palm creases and buccal mucosa due to the increased production of pituitary ACTH and other pro-opiomelanocortin-related peptides. Resistance to stress is lowered and sensitivity to infections increased. There is often pronounced intolerance of cold and the body temperature is usually low. Symptoms of hypoglycaemia may appear at higher levels of blood sugar than is usual. There is an increased liability to convulsions, and the EEG is often abnormal with diffuse high-amplitude slow activity. Very occasionally, potassium retention may lead to hyperkalaemic periodic paralysis and may be the sole presentation (see Potassium depletion, later).

As many as half of all patients diagnosed with Addison's disease may present with a life-threatening adrenal crisis (Zellisen 1994), a medical emergency characterised by profound hypotension or hypovolaemic shock, acute abdominal pain, vomiting and often fever, that may be prevented if early diagnosis is made. It may occur spontaneously or in response to infection or drugs such as morphine or anaesthetic agents.

Psychiatric features

Psychiatric abnormalities are present in almost all patients with Addison's disease. The commonest changes are similar to those expected in chronic physical exhaustion: depres-

sion, emotional withdrawal, apathy and loss of drive and initiative. There are sometimes sudden fluctuations of mood, or episodes of marked anxiety and irritability. Cleghorn (1965) described mental symptoms of apathy and negativism in 80% of cases, depressive withdrawal and irritability in 50%, whilst suspiciousness was seen in 15%, agitated behaviour in 10% and paranoia with delusions in 5%. Memory impairment also occurs in up to three-quarters of cases (Michael & Gibbons 1963). Mild dementia may be simulated on account of the mental anergia, poverty of thought and general air of indifference. Considerable perceptual impairment may also be seen, with increased thresholds to tactile, auditory and olfactory stimuli (Leigh & Kramer 1984). Drowsiness can be conspicuous, although increased irritability, restlessness and insomnia are also seen. The severity of the changes may fluctuate over time, varying directly with the severity of the endocrine disorder.

Psychotic pictures of a depressive or schizophrenic nature are rare, in contrast to the clinical picture in Cushing's disease. However, Cleghorn (1951) reported examples of acute and chronic paranoia, hallucinatory states and schizophreniform psychoses. Such disturbances may be very short-lived and are sometimes intimately related to impending crises. McFarland (1963) reviewed reports of 10 patients with schizophrenia, six with affective psychosis and one with organic psychosis and concluded that the form of psychotic development was unpredictable. One of his patients presented with hypomania that masked the adrenal disorder until the patient lapsed into coma after electroconvulsive treatment, when severe hyponatraemia was discovered.

Investigation

Addison's disease must be differentiated from hypopituitarism and from other chronic debilitating diseases. Weight loss, hypotension and pigmentation may all be seen, for example, in carcinoma, tuberculosis, malabsorption or malnutrition. It is therefore essential to investigate adrenal function adequately before making the diagnosis.

Hyponatraemia is present in about 90% of cases of primary adrenal insufficiency, and hyperkalaemia in 65% (Kong 1994); thus normal serum sodium and potassium values do not preclude the diagnosis. The simultaneous measurement of early-morning serum cortisol and plasma ACTH separates primary adrenal insufficiency from normals or those with secondary disease (Oelkers 1992). In primary adrenal failure plasma ACTH is usually greatly increased, with a low or low-normal cortisol. Alternatively, the synthetic ACTH (tetracosactide, Synacthen) test may be used. This will show a failure of serum cortisol response at 30 or 60 minutes after injection of 250 µg of tetracosactide in primary adrenal failure whereas in secondary hypoadrenalism the response may be delayed. The insulin tolerance test is regarded as the gold standard for the assessment of

suspected secondary adrenal deficiency (Arlt & Allolio 2003). Assessment of adrenal cortex autoantibodies, especially those directed against 21-hydroxylase, may also be helpful especially in suspected isolated primary adrenal insufficiency.

From the psychiatric point of view an erroneous diagnosis of a neurotic or stress-related disorder or early dementia may easily be made. The depression and generalised weakness may be attributed to neurasthenia, especially when pigmentation is slight and serum electrolytes are normal. The impression of a neurotic or stress-related disorder is strengthened by the anorexia, irritability and diminished libido, and by the fluctuation of symptoms over time. Dementia, or a chronic amnesic syndrome, is suggested when memory difficulties are prominent.

Treatment and outcome

Chronic glucocorticoid replacement with hydrocortisone is usually given in two or three daily doses, with the majority given in the morning to mimic physiological secretion patterns. Mineralocorticoid replacement in primary adrenal failure is with fludrocortisone. Adrenal androgen replacement with DHEA is not current clinical practice. Adequate replacement therapy is usually highly successful in alleviating most physical and mental disturbances. The patient's sense of well-being quickly improves, and appetite and energy gradually return to previous levels. Glucocorticoids appear to be more important than mineralocorticoids for reversing the mental symptoms and abolishing the EEG abnormalities, indicating that these do not rest entirely on disturbances of electrolyte and water balance (Reichlin 1968). Whether current therapy with glucocorticoids and mineralocorticoids abolishes all the symptoms of Addison's disease or whether a lack of androgens is associated with increased fatigue, reduced vitality perception and well-being or with subtle cognitive deficits is currently debated (Lovas *et al.* 2002; Riedel 1993). A number of randomised placebo-controlled trials of DHEA replacement have reported conflicting effects on subjective health status, mood and sexuality (Arlt *et al.* 1999; Hunt *et al.* 2000; Johannsson *et al.* 2002; Lovas *et al.* 2003). A precise definition of the clinical syndrome of DHEA deficiency would allow more sensitive and disease-specific instruments to be developed and the benefits or not of replacement to be assessed (Lovas *et al.* 2003).

Malnutrition

Severe chronic malnutrition is accompanied by well-described psychological changes: apathy, emotional lability and impairment of memory. Confusional states are not uncommon though acute psychosis is rare. Much of the early literature on the effects of chronic severe malnutrition came

from studies of survivors of the Nazi concentration camps and prisoner of war camps in Germany, Russia and the Far East (Helweg-Larsen *et al.* 1952; Thygesen 1970). These suggested that neurotic symptoms did not develop and antecedent psychoneurotic and compulsive symptoms disappeared, with interest becoming focused on food alone (Thygesen *et al.* 1970).

At 23-year follow-up of Danish concentration camp survivors, Thygesen *et al.* (1970) showed that fatigue, depression, lability of affect, sleeplessness with nightmares, and reduction in learning capacity and concentration were common and suggested that with time these may fade into a state of premature senescence with intellectual reduction and associated cerebral atrophy. Others have also shown an increase in the late development of spinal cord lesions and parkinsonism that cannot be ascribed to the late effects of known tropical diseases or specific vitamin deficiencies (Gibberd & Simmonds 1980). However, the combination of severe malnutrition with chronic emotional stress in these groups makes it difficult to isolate the specific effects of malnutrition from those associated with comorbid post-traumatic stress disorder, which is now recognised to be common in these groups (Sutker *et al.* 1993) and is associated with very similar symptoms.

There has since been debate about whether chronic severe malnutrition predisposes to an increased risk of subsequent accelerated cognitive decline and dementia. Sutker *et al.* (1990, 1992) found specific deficits in tests of attention, concentration and memory as well as on abstraction and organisation in former prisoners of war that was most marked in those with weight loss of more than 35% of total body weight. These findings have been questioned by Sulway *et al.* (1996) who found no significant differences in cognitive performance on a battery of neuropsychological tests or of the prevalence of dementia in a group of Australian prisoners of war compared with Second World War veterans regardless of magnitude of weight loss. They argued that their failure to show cognitive deficits was due to more closely matched controls and suggested that previously found cognitive deficits may be due to an increased incidence of depression seen in prisoners of war that appears to decrease with age. A more recent case-control study of prisoners of war repatriated from North Vietnam also failed to show a significant difference on neuropsychometry compared with naval controls (Williams *et al.* 2002).

In infants and young children, on the other hand, there is firmer evidence that starvation is liable to damage the brain. Rodent studies showed that growth retardation induced by protein-energy malnutrition during suckling was not entirely reversed with subsequent feeding (Dobbing 1990; Levitsky & Strupp 1995) and pathology showed evidence of permanent cortical injury, with reduction in the density and arborisations of dendrites and abnormal myelination and width of cortical cells. Neurotransmitter systems were

also altered permanently, for example the number of noradrenaline receptors was reduced compared with controls (Levitsky & Strupp 1995). All brain regions appear to be vulnerable. Cravioto and Delicardie (1970) showed a difference in IQ in malnourished children compared with their adequately nourished siblings, helping to confirm that the differences in cognitive function are due mainly to early malnourishment rather than differences in their psychosocial environment, and there have now been so many well-controlled studies from many countries worldwide that the severe cognitive effects of early life malnutrition are no longer in doubt (Scrimshaw 1998; O'Connor *et al.* 2000). Pollitt (2000) has reviewed longitudinal studies of the cognitive effects of supplementary feeding at different periods of early life and tentatively concludes that supplementary feeding during the first 18–24 months of life may help to prevent part of the cognitive delays caused by extreme poverty and malnutrition. Beyond this period the developmental benefits of supplements vary as a function of the breadth of intervention, e.g. nutrition, health, education and duration of intervention. Current studies are investigating the consequences of malnutrition on emotional and motor development and interrelation between these variables.

Under normal circumstances malnutrition of this degree is rarely encountered in Western societies. However, even in populations where the general standard of nutrition is high there are groups prone to inadequate or imbalanced food intake who may present with vitamin depletion. Those with learning disabilities or chronic mental illness and the homeless often live precariously in the community and vitamin deficiencies may add to their symptomatology. The aged population is similarly at risk, especially when depression or early dementia impairs standards of self-care. Individuals with alcohol dependency face the multiple hazards of inadequate intake, poor absorption and special demands made on vitamin reserves for the metabolism of alcohol. These are all groups that are particularly liable to come to psychiatric attention. Patients with chronic gastrointestinal disease and malabsorption are another group at risk, while any physical illness may deplete reserves. Profound deficiencies may be revealed postoperatively, especially in patients maintained for a considerable time on intravenous fluids.

Of all the vitamins it is the members of the B complex, particularly thiamine and nicotinic acid, that have proved to be of most importance in psychiatric practice. Other deficiencies will often coexist in chronic malnutrition, but specific roles for vitamins A, C and D have not been clearly identified in relation to mental disorder. Vitamin B₁₂ and folic acid have been increasingly studied in relation to psychiatric illness and this evidence is also reviewed. Vitamin E has also been increasingly implicated in the aetiology of Parkinson's disease (see Chapter 12).

Vitamin B deficiency

Laboratory studies provide a firm basis for expecting functional and pathological changes in the CNS as a result of vitamin B deprivation. Many components of the B complex are known to play an essential role in metabolic processes within the brain: thiamine pyrophosphate is a coenzyme involved in carbohydrate metabolism, particularly the oxidation of pyruvate, and may also be necessary for the proper transmission of nerve impulses; nicotinic acid and its amide act as constituent parts of coenzymes necessary for glucose metabolism; riboflavin acts similarly; pantothenic acid is concerned with the formation of acetylcholine; and pyridoxine becomes converted into pyridoxal phosphate, a coenzyme fundamental to several enzyme systems concerned in brain metabolic processes.

It was not until the 1930s that the full significance of vitamin B deficiency in relation to psychiatric disorder began to be appreciated, although mental disorder had been recognised as an integral part of the syndrome of pellagra from its earliest descriptions. In the 1930s, however, the various constituents of the B complex were identified, and careful observation soon extended awareness of their functions. Experimental studies showed that deprivation could lead to psychological symptoms well before definitive manifestations were declared in other systems of the body. Acute and severe depletion of vitamin reserves also proved to be responsible for fulminating neuropsychiatric disorders that had not previously been thought to be nutritional in origin.

The wide natural dispersion of the B vitamins has made it difficult to work out precise relationships in naturally occurring disorders, and multiple deficiencies will often operate together. Sometimes, however, the evidence linking specific deficiencies to specific clinical pictures has been clarified by noting the therapeutic response to vitamins given singly. Thiamine and nicotinic acid have emerged as the vitamins of greatest importance in neuropsychiatric disorders, with others such as pyridoxine, pantothenic acid and riboflavin contributing mainly to ancillary symptoms. Moreover, with both thiamine and nicotinic acid it is clear that different syndromes of deficiency can follow, depending on the severity of depletion and the time over which it has operated.

Thiamine (B₁) deficiency classically leads to beriberi, with neuropathy, cardiac failure or peripheral oedema. This clinical picture results from chronic severe depletion. In the shorter term a neurasthenic picture may result, with fatigue, weakness and emotional disturbance, well before the physical features appear. Acute and fulminant depletion can lead to the picture of Wernicke's encephalopathy. This probably occurs through a combination of dietary insufficiency, impaired intestinal absorption and possibly a genetically determined abnormality of transketolase (Mukherjee *et al.*

1987) in the context of low bodily stores. The changes in Wernicke's encephalopathy may be confined to the CNS, and other evidence of vitamin lack may be entirely absent. See Chapter 4 (Wernicke's encephalopathy, Korsakoff's syndrome) for further discussion on the neuropsychiatric consequences of thiamine deficiency.

Nicotinic acid (niacin) deficiency shows a similar range of disorders. Subacute deficiency produces the syndrome of pellagra, with gastrointestinal symptoms, skin lesions and psychiatric disturbance. In the early stages a neurasthenic picture may be seen in relative isolation. Acute and sudden depletion may lead to a picture of 'encephalopathy', sometimes with few or no symptoms or signs in other systems to point to vitamin deficiency.

Pyridoxine (B₆) deficiency can lead to convulsions in infants on deficient diets or in those with unusually high requirements. Pronounced abnormalities appear in the EEG and mental deterioration may develop. Symptoms and the EEG changes may resolve within minutes of injection of the vitamin. Lack of pyridoxine may also contribute to the neuropathy seen with severe malnutrition. Experimental deficiency in adults, or the use of pyridoxine antagonists, leads to irritability, confusion and lethargy (Fabrykant 1960). Some authors have suggested that pyridoxine deficiency may contribute to depressive illness (Carney *et al.* 1979, 1982). Among patients admitted to a psychiatric unit, deficiencies of pyridoxine, and perhaps of riboflavin, were present in a higher proportion of those with affective disorder than with other psychiatric conditions. Pyridoxine deficiency has also been implicated in premenstrual syndrome and depression in patients taking oral contraceptives. Systematic review by Wyatt *et al.* (1999) concluded that doses of vitamin B₆ up to 100 mg daily are likely to be of benefit in treating premenstrual symptoms and premenstrual depression, with odds ratios compared with placebo of 2.32 and 1.69 respectively. However, these authors commented that these conclusions were limited by the low quality of most of the trials included.

Riboflavin (B₂) deficiency is characterised by sore throat, glossitis, angular stomatitis, lacrimation, photophobia, seborrhoeic dermatitis, and a normochromic normocytic anaemia. In study of severe and specific riboflavin restriction in healthy volunteers, Sterner and Price (1973) found personality changes on the Minnesota Multiphasic Personality Inventory (MMPI) that appeared to reflect increasing lethargy, hypersensitivity and a multitude of minor somatic complaints; however, these findings have not been replicated (Powers 2003). Subclinical riboflavin deficiency may contribute to increased concentrations of plasma homocysteine, with an associated increased risk of cardiovascular disease, and it may also be associated with impaired handling of iron and night blindness.

Pantothenic acid deficiency has been incriminated in leading to sensory neuropathy and the 'burning feet' syndrome. However, as in the case of riboflavin, a role in naturally occurring neurological or psychiatric disorder has not been clearly established.

Various aspects of vitamin B deficiency may prove to be commoner than expected among a wide range of psychiatric patients (Carney *et al.* 1982). Among 172 successive admissions to a psychiatric unit, 30% were considered to be deficient in thiamine, 27% in riboflavin and 9% in pyridoxine as assessed by red cell enzyme functions. More than half were deficient in at least one of the three, despite being drawn from a reasonably affluent community. Thiamine deficiency was mainly found in patients with alcohol dependency, drug addiction, schizophrenia and depression where poor diet may be expected. In contrast, those with pyridoxine deficiency often showed little evidence of malnutrition, and there was a significant association with depressive illness. Controlled studies examining the role of folate deficiency and homocysteine for example will be required to determine whether such vitamin deficiencies may sometimes play an aetiological role in the genesis of depressive disorder, or whether they contribute more widely to psychiatric morbidity.

A number of studies have kept volunteer subjects on diets deficient in B vitamins in order to determine the earliest clinical features associated with deficiency. The findings are in broad agreement, particularly in emphasising the prominence of mental symptoms. Brozek and Caster (1957) confirmed the psychological effect of severe thiamine depletion using more precise dietary techniques. General weakness and extreme anorexia were associated with marked irritability and depression, and scores on the hysteria, hypochondriasis and depression scales of the MMPI deteriorated considerably. Continuation of the diet led ultimately to peripheral neuropathy and impairment on tests of manual speed, coordination and reaction time, but general intelligence was unaffected. The reintroduction of thiamine restored appetite promptly and produced a dramatic change in the attitude of the subjects, with a slower improvement in peripheral neuropathy.

Mental changes in pellagra

Multiple vitamin deficiencies or an imbalance in dietary amino acids may be operative in pellagra, although lack of nicotinic acid is by far the most important and replacement can lead to rapid relief of symptoms. Endemic pellagra disappeared with the improvement in nutritional education and widespread supplementation of grain cereals with nicotinic acid. It is now seen sporadically in patients with chronic alcoholism and poor nutritional status (Ishii & Nishihara 1981) or rarely in the malnourished homeless (Kertesz 2001). It is also a rare manifestation of the carcinoid syndrome, in

which up to 60% of tryptophan is catabolised by what is usually a minor pathway, and of Hartnup disease, an inherited disorder in which several amino acids including tryptophan are poorly absorbed from the diet. In both conditions symptoms of pellagra may be cured by the administration of large amounts of niacin.

The characteristic triad of pellagra includes gastrointestinal disorder, skin lesions and psychiatric disturbance. The commonest gastrointestinal disturbances are anorexia and diarrhoea and vomiting. Skin changes are classically bilateral and symmetrical, presenting in sun-exposed areas and may include vesicles or bullae on extremities and desquamation and roughening of the skin on the dorsum of the hands. Eczema-like lesions around the mouth and nose and stomatitis are also often seen (Ishii & Nishihara 1981).

Prodromal features are similar to those seen in experimental thiamine deficiency. General deterioration of mental and physical health may predate more definite manifestations by weeks or months. Most prominent is a subjective feeling of incapacity for mental and physical effort, coupled with numerous other vague complaints: anorexia, insomnia, nervousness, apprehension, dizziness, headache, palpitations and paraesthesiae. Characteristically these fluctuate markedly from day to day. Irritability and emotional instability may dominate the picture. Depression can be severe with considerable risk of suicide. At a later stage the mental processes are obviously impaired, memory is poor and confabulation may appear. Such changes were well described in areas where pellagra was previously endemic, and patients themselves often recognised them as prodromes of the more florid manifestations of the disease. However, the rarity of pellagra today means that they are often misconstrued when sporadic cases arise.

More prolonged and severe nicotinic acid deficiency leads to the florid psychiatric manifestations of pellagra. These may sometimes develop without the above prodromes. They are often associated with gastrointestinal and skin changes but may occur alone or dominate the picture. The commonest presentation is an acute organic reaction with disorientation, confusion and impairment of memory. Excitement and outbursts of violent behaviour may occur, depression is often conspicuous, or paranoia may develop with hallucinations and delusions of persecution. Occasionally, chronic untreated pellagra may progress with a picture similar to Korsakoff's syndrome or as a slowly progressive generalised dementia. A neuropathological series by Ishii and Nishihara (1981) emphasises the importance of considering a diagnosis of pellagra in chronic alcoholism even in the absence of the classical skin changes. Of 74 patients with chronic alcoholism, 20 had neuropathologically diagnosable pellagra, of whom 19 had been diagnosed with delirium tremens at admission, presenting with confusion, hallucinations, insomnia, gait disturbance and

incontinence of urine and faeces. Only six had evidence of skin lesions.

Acute psychosis also responds to nicotinic acid, often in a dramatic fashion with calm and rational behaviour restored within a few days of vitamin replacement and occasionally within hours. It is very rare for treatment to fail in acute presentations, though the response in chronic cases with severe mental impairment may be less successful (Spies *et al.* 1938; McLester 1943). Neurological disturbances such as tremor, ataxia and sometimes dysarthria and dysphagia develop late in the course. A sensorimotor peripheral neuropathy is common, with paraesthesiae, pain and tenderness, chiefly in the distal leg muscles.

The early symptoms of pellagra are not associated with morphological changes within the brain and are presumed to depend on reversible biochemical changes within neurones. However, established pellagra is associated with a characteristic pathology: ballooning of the cell wall with loss of Nissl substance and compression of the nucleus to one side, affecting especially Betz cells in the motor cortex (Meyer 1901) and pontine, dorsal vagal and other brainstem nuclei (Leigh 1952). Symmetrical demyelination of the posterior fasciculus gracilis and cuneus, and to a lesser extent crossed pyramidal and spinocerebellar tracts, may also be seen (Spillane 1947). Degeneration of myelin in peripheral nerves has also been found (Wilson 1940).

Hartnup disease

Pellagra-like features occur as episodic attacks during childhood, then tend to subside during adult life. Increased renal clearance of neutral amino acids, including tryptophan, is accompanied by defective absorption of tryptophan from the gut. Some cases are asymptomatic and discovered only on routine screening. Other patients present with a photosensitive skin rash, often accompanied by psychiatric disturbance, cerebellar ataxia or other neurological abnormalities. Oral nicotinamide helps substantially during attacks, though these tend to subside spontaneously. Psychiatric features range from emotional lability in the milder cases to apathy, irritability, depression, confusion and delirium in the more marked examples (Hersov & Rodnight 1960). The coexistent photosensitive skin rash is an important clue to the underlying biochemical abnormality.

Acute nicotinic acid deficiency encephalopathy

Literature from the 1930s and 1940s described a syndrome of various forms of acute organic reaction that showed an excellent response to large doses of nicotinic acid. The clinical picture was of stupor or delirium, often dramatic in development and carrying a high mortality. Weakness and lethargy were common but anxiety and agitation could be marked. Extrapyramidal features, with cogwheel rigidity, and grasping and sucking reflexes were frequent accompaniments. Glossitis or stomatitis was frequently but not

always present. In some the neuropsychiatric picture was the sole manifestation. Most patients had a history of malnutrition in combination with a history of chronic alcohol abuse. Thiamine replacement had no effect on the clinical picture but nicotinic acid in large dosage produced recovery usually in 3–5 days. Mortality was drastically reduced by such treatment, from 90% to 14%. Those who survived were often left with memory deficits.

The contemporary rarity of this syndrome in the UK and North America is probably associated with the routine use of high-potency vitamin therapy in the management of patients presenting with alcohol dependency (Lishman 1981). Reports from Japan and elsewhere suggest that the syndrome may still exist in the chronically malnourished and emphasise the importance of high-potency multivitamin replacement in all patients with chronic alcohol abuse or in whom chronic malnutrition may be suspected for other reasons (Ishii & Nishihara 1981; Kertesz 2001).

Ishii and Nishihara suggest that when an alcoholic patient develops neurological signs, particularly extrapyramidal rigidity, in addition to mental and gastrointestinal symptoms, nicotinic acid deficiency must be strongly suspected even in the absence of skin lesions. Gait disturbance, incontinence and hyperreflexia are further important features differentiating the syndrome from uncomplicated delirium tremens. In many cases it may be expected that thiamine deficiency will also be operative; however, only two of Ishii and Nishihara's 20 patients showed the pathology of Wernicke's encephalopathy in addition to that of pellagra. Similar findings were reported in 33 patients with chronic alcohol dependency from France (Hauw *et al.* 1988; Serdaru *et al.* 1988). Neurological features included marked oppositional hypertonus (*gegenhalten*) myoclonus, confusion and clouding of consciousness. At autopsy, chromatolysis was observed in neurones of the brainstem and cerebellar dentate nuclei, typical in all respects of nicotinic acid deficiency.

Vitamin B₁₂ deficiency

Pernicious anaemia is widely recognised to be associated with subacute combined degeneration of the cord but it may also be accompanied by abnormalities of the mental state. This was probably recognised by Addison in his initial description of 'fatal idiopathic anaemia' in which he stated that 'the mind occasionally wanders' (Addison 1849). Langdon drew attention to these changes in 1905 with reports of loss of inhibition, peevishness and general mental deterioration in patients with pernicious anaemia. Of his nine patients, one was depressed, one institutionalised and another had been 'mentally peculiar' for 2 years with auditory hallucinations. It has been suggested that some of the mental symptoms, such as apathy and somnolence, may be related to the anaemia associated with vitamin B₁₂ deficiency (Shulman 1967), whereas others including affective disorder,

schizophrenia, paranoia, episodes of disorientation and delirium, and progressive dementia have been attributed directly to the B₁₂ deficiency (Holmes 1956). Renewed interest in the cerebral manifestations of pernicious anaemia followed the work of Holmes (1956) and Smith (1960) which showed that they were not infrequent and responded rapidly to vitamin B₁₂ replacement. These manifestations also emphasised that mental symptoms may occasionally be seen many months or even years before the development of anaemia or of peripheral neurological manifestations.

Surveys of psychiatric populations have often shown a large number of patients with low serum B₁₂ levels. Recent studies have suggested that serum B₁₂ levels have limited sensitivity for detecting clinically meaningful cobalamin deficiency in tissue and, as discussed below in the introduction to the section on folate, other measures may be more sensitive. Elevated serum levels of methylmalonate and total homocysteine, the accumulated substrates of two important cobalamin-dependent reactions, indicate tissue deficiency of cobalamin even in some patients with normal serum cobalamin levels (Savage *et al.* 1994). Recent studies in elderly non-hospital populations using these combined measures identified tissue deficiency of cobalamin in 5–23%, with reliance on serum B₁₂ levels alone underestimating tissue deficiency by up to 50% (Hutto 97; Clarke *et al.* 2004).

An additional difficulty is that the low levels of B₁₂, or alteration in the levels of methylmalonic acid or homocysteine, may be the consequence rather than the cause of the abnormal mental state, since B₁₂ deficiency can result from inadequate nutrition. However, daily requirements of B₁₂ are small and it would normally take many years before simple dietary lack would become manifest in this way. Nevertheless, a low serum iron or folic acid can contribute to lowering of the serum B₁₂, which may therefore result from a mixed nutritional deficiency in patients with depression or dementia who have neglected their diet.

In an attempt to resolve this, Zucker *et al.* (1981) reviewed numerous case reports in the literature, using strictly defined criteria before accepting a causal link between B₁₂ deficiency and psychiatric disturbance. They identified 15 patients where the relationship seemed well established. Among their requirements were the absence of other organic causes for the mental symptoms, a non-relapsing course, poor response to other treatments, and a positive and well-maintained response to B₁₂ administration. Criteria for the diagnosis of B₁₂ deficiency were also specified with care. The psychiatric pictures in the patients identified were heterogeneous, with a preponderance of organic mental symptoms, depression, paranoia, irritability and episodes of assaultative behaviour. Marked psychiatric disorder could sometimes occur in the absence of neurological abnormalities or anaemia.

Neurological symptoms have previously been considered a late manifestation of B₁₂ deficiency, typically occurring

after the development of anaemia. Lindenbaum *et al.* (1988) reviewed 141 consecutive patients with neuropsychiatric abnormalities due to cobalamin deficiency and found that 28% had no anaemia or macrocytosis. The haematocrit was normal in 34, mean cell volume was normal in 25, and both tests were normal in 19. Characteristic features in such patients included paraesthesiae, sensory loss, ataxia, dementia and psychiatric disorders. Methylmalonic acid and total homocysteine were also markedly elevated in these patients. Serum cobalamin levels were above 150 pmol/L in two patients, between 75 and 150 pmol/L in 16, and below 75 pmol/L in only 22. Except for one patient who died during the first week of treatment, all these patients showed an improvement in their mental state in response to vitamin B₁₂ replacement. The authors concluded that neuropsychiatric disorders due to cobalamin deficiency occur commonly in the absence of anaemia or an elevated mean cell volume and that measurement of serum methylmalonic acid and total homocysteine were useful in the diagnosis of these patients.

Mood disorders

The role of vitamin B₁₂ in the facilitation of monoamine transmitter release and the mechanism by which low levels may lead to depressed mood have been discussed above and have led to a renewed interest in the role of vitamin B₁₂, folate, homocysteine and other components of one-carbon metabolism in the aetiology of depression. Epidemiological studies have found that up to 31% of depressed patients have low serum vitamin B₁₂ levels, though many have been criticised for lack of a consistently defined cut-off or clear or consistent control groups (Hutto 1997).

Overall the evidence supporting an association between vitamin B₁₂ deficiency and depression remains quite sparse. With the exception of one study (Levitt & Joffe 1993), most studies in non-elderly groups have found no correlation between cobalamin levels and depression measured with the Hamilton Depression Scale. Studies in elderly groups have provided slightly stronger data. A community study of physically disabled women aged over 65 years found that subjects with B₁₂ deficiency were twice as likely to be severely depressed as non-deficient controls (Penninx *et al.* 2000). The Rotterdam community study screened 3884 elderly people for depressive symptoms, with those positive to the screen undergoing assessment with the Present State Examination. Hyperhomocysteinaemia, vitamin B₁₂ deficiency and to a lesser extent folate deficiency were all related to depressive disorders; however, only the association with B₁₂ remained significant after adjustment for functional disability and cardiovascular disease (Tiemeier *et al.* 2002).

Conversely, the Hordaland homocysteine cross-sectional study failed to find an association between low vitamin B₁₂ levels and depression or anxiety disorder in approximately 6000 middle-aged and elderly subjects (Bjelland *et al.* 2003). However, the study did identify a significant association of

hyperhomocysteinaemia and the T/T methylenetetrahydrofolate reductase (MTHFR) genotype (which is associated with elevated homocysteine levels under low folate conditions) with depression without comorbid anxiety. These studies and others increasingly suggest a role for components of the 1-carbon metabolic pathway in depression, although further studies will be required to dissect the contributions of individual components.

Psychosis

Case reports and case series over many years have associated psychotic symptoms with vitamin B₁₂ deficiency. Early case series reported incidences of psychosis in 0–16% of patients with pernicious anaemia (Woltman 1924; Herman & Rost 1937); however, in a prospective study of 27 patients with pernicious anaemia none developed psychosis (Shulman 1967). In their review of B₁₂ deficiency and psychiatric disorders, Zucker *et al.* (1981) found that 10 of 15 cases presented with psychiatric symptoms, all of whom had paranoid delusions, seven had hallucinations (one visual, three auditory and three both visual and auditory), seven were depressed and six had some organic features. One study showed that patients with psychotic depression had significantly lower mean vitamin B₁₂ levels compared with patients with non-psychotic depression (Levitt & Joffe 1988). Whether vitamin B₁₂ deficiency contributes to the development of psychosis, is a precipitant in predisposed individuals, is a coincidental finding or is a consequence of secondary nutritional origin remains unclear.

Other organic psychiatric disorders

In Shulman's (1967) prospective study, approximately three-quarters of the patients with pernicious anaemia showed anterograde memory deficits on a simple learning test. Retesting after treatment showed that the majority had returned to normal, sometimes within 20 hours of the first injection. Eastley *et al.* (2000) reported on 1432 patients seen at the Bristol memory clinic over a 13-year period; 125 had a low serum B₁₂, 66 presenting with a dementing illness and 22 with mild cognitive impairment. In this case-control design, none of the DSM-III diagnosed dementia group showed a significant improvement in neuropsychological function on replacement therapy; however, those presenting with cognitive impairment showed a significant improvement in verbal fluency compared with controls, with non-significant improvement on other measures.

Whilst absolute or functional B₁₂ deficiency appears to be relatively common, especially in the elderly population with evidence to suggest reversal of mild cognitive deficits and other neuropsychiatric features, deficiency of B₁₂ is a remarkably rare cause of a reversible dementia. Reversible dementias account for approximately 1% of all-cause dementia (Walstra *et al.* 1997), of which vitamin B₁₂ deficiency has been implicated in approximately 1% (Clarfield 1988). Chiu's

(1996) review of the literature identified only 14 papers published between 1966 and 1995 reporting on cognitive impairments or dementia attributable to B₁₂ deficiency and their response to treatment. She could identify only 10 patients in this literature with dementia who significantly improved or resolved with B₁₂ treatment. Whether this is because changes associated with long-standing disease, as compared with milder presentations, lead to treatment resistance or simply because B₁₂ deficiency was an association but not causative cannot be determined.

Neurological accompaniments

Numbness of the extremities is the commonest early symptom described in all series. Patients may also complain of tingling, pins and needles, 'feet going to sleep', burning or other dysaesthetic sensations (Victor & Lear 1956). Paraesthesiae are generally symmetrical and usually start, or are more severe in, the feet than the hands. Other more unusual symptoms, such as coldness, stiffness, band-like sensations, wetness or tightness, may also be described (Victor & Lear 1956). Motor weakness and sensory ataxia may be described as fatigability and unsteadiness when walking.

Neurological signs were detailed by Healton *et al.* (1991) who reviewed 143 patients seen in two large centres over an 18-year period. Neurological signs were seen in 80%. Of these, diminished peripheral vibration sense was the most common sign, seen in nearly 90%, and best detected with a 256-Hz tuning fork (Herbert 1988). Impaired proprioception occurred only in those with diminished vibration sense. Cutaneous sensation was impaired in only four subjects where vibration sense was intact and a further two cases showed ataxia in the absence of impaired vibration sense. Weakness of the limbs, always in association with sensory deficits, and symmetrical in all but one case was seen in only 16. An extensor plantar reflex was found in 17 of 153. Deep tendon reflexes were unhelpful; increased, normal and decreased reflexes were all seen. Mental impairment, which earlier studies associated with more severe and prolonged deficiency, was seen in 18. These findings emphasise the importance of a thorough neurological examination including vibration sense testing in all patients suspected of vitamin B₁₂ deficiency. The finding of these symptoms and signs without other identified cause arouse the suspicion of subacute combined degeneration of the cord in any psychiatric patient.

Pathology and other investigations

Pathological findings in the brains of patients dying with pernicious anaemia have been described since early in the twentieth century (Pfeiffer 1915). Adams and Kubik (1944) showed that the cerebral findings in patients with symptoms of suspiciousness, memory loss and confusion were similar to those seen in the spinal cord in subacute combined degen-

eration. EEG abnormalities are seen in a high proportion of cases of confirmed pernicious anaemia (Walton *et al.* 1954; Kunze & Leitenmaier 1976): mild abnormalities show as excessive slow activity, severe abnormalities as delta activity that is sometimes paroxysmal or focal. These abnormalities appear to bear no simple relationship to the severity of the anaemia but instead appear to reflect a specific defect of cerebral metabolism. Abnormal somatosensory-evoked potentials are frequently seen in subtle vitamin B₁₂ deficiency, showing a pattern that suggests a central abnormality in at least half (Jones *et al.* 1987; Karnaze & Carmel 1990). The majority of EEG abnormalities are reversible with treatment, sometimes starting within 7–10 days of the first B₁₂ injection. The few cases published also suggest an improvement in central and possibly peripheral somatosensory-evoked potential abnormalities with treatment. Structural T2-weighted MRI in a patient with pernicious anaemia and a 4-month history of progressive cognitive decline showed extensive areas of high-intensity signal in the periventricular white matter (Scherer 2003). A study using tensor-diffusion imaging in a similar patient showed reduced anisotropy in periventricular white matter tracts, suggesting that B₁₂ deficiency was associated with white matter tract disruptions in this region (Kealey & Provenzale 2002).

Early metabolic studies also revealed impaired uptake of oxygen and glucose by the brain, especially in the presence of mental symptoms such as forgetfulness, confusion and disorientation, which again responded to replacement therapy (Scheinberg 1951). These were also unrelated to the severity of anaemia, appearing to be a specific result of B₁₂ deficiency which suggests that similar disturbances of metabolism may occur in patients with low serum B₁₂ even in the absence of pernicious anaemia. There appear to have been no modern studies using either functional MRI or PET that have investigated the effect of vitamin B₁₂ deficiency on cerebral functioning.

These observations emphasise the importance of considering B₁₂ deficiency in the differential diagnosis of all patients with unexplained acute organic reactions or cognitive impairment, and to pursue treatment vigorously at the earliest opportunity.

Routine screening

Currently there are no clear guidelines for the screening of patients presenting with psychiatric or cognitive disorders or the healthy elderly in whom high prevalences of individual or combined B₁₂ and folate deficiencies have been described (Clarke *et al.* 2004). Chiu (1996) had suggested that all patients presenting with any degree of cognitive impairment be screened, especially if they have neurological or mild haematological signs of B₁₂ deficiency. Within other psychiatric groups the situation is less clear, though it would seem sensible to consider B₁₂ measurement in any patient presenting with abnormal mental state in association with

neurological signs such as unexplained impaired vibration sense or haematological changes such as anaemia, macrocytosis or neutrophil hypersegmentation. Any psychiatric patient with a history of gastric surgery or patients with regional ileitis or malabsorption syndromes such as steatorrhoea should also be screened. Low B₁₂ levels are also common in vegans.

A further difficulty is determining which of the factors important in one-carbon metabolism to measure. Interactions between vitamin B₁₂, folate, homocysteine, methylmalonate, S-adenosylmethionine (SAM) and other components may lead to recommendations that multiple components be measured to obtain a clear picture of deficiency in any individual.

Treatment

Uncomplicated pernicious anaemia should be treated with intramuscular injections of hydroxocobalamin 1 mg three times a week for 2 weeks to replenish stores, then 1 mg every 3 months. With subacute combined degeneration of the cord, twice the loading dose is given in the early weeks of treatment, and this is equally advisable in patients with suspected cerebral involvement.

Folic acid deficiency

Folate, vitamins B₁₂, B₆ and B₂ and homocysteine, a sulphur-containing amino acid, are all components of the biochemical reactions involved in one-carbon metabolism. Accumulated data from the last four decades have implicated some or all of these components in abnormal development of the nervous system, in the increased risk of neurodegenerative conditions including stroke, Alzheimer's disease and Parkinson's disease, and in the pathogenesis of a number of psychiatric disorders, particularly folate in depression. A better understanding of the role of these individual components in neuronal homeostasis has led to new insights into the mechanisms through which deficiency of individual elements may disrupt these homeostatic mechanisms and lead to CNS dysfunction with consequent symptom expression.

The amino acid methionine plays a central role in one-carbon metabolism, a series of biosynthetic pathways crucial for DNA synthesis and repair and numerous other methylation reactions. Dietary methionine alone is insufficient to meet all of the body's methylation (one-carbon) requirements and additional methionine must be generated *de novo* from the one-carbon folate pool. Folate converts methionine to SAM, which is the major donor for most methyltransferase reactions. When folate levels are low, SAM is depleted. This leads to reduced DNA cytosine methylation, which results in hypomethylated DNA and enhanced gene transcription, and DNA strand breakage and may impair DNA repair mechanisms, leading to genetic mutations or the trig-

gering of apoptosis (Mattson & Shea 2003). SAM also plays a role in the methylation of proteins, phospholipids and neurotransmitters.

Folate and vitamin B₁₂ are also cofactors in the re-methylation of homocysteine to methionine and deficiency of either may lead to increased homocysteine levels. The nervous system has been shown to be particularly sensitive to extracellular homocysteine, which promotes neuronal excitotoxicity via stimulation of N-methyl-D-aspartate (NMDA) receptors and increases oxidative stress that results in neuronal DNA damage and triggering of apoptosis. For further details on the role of folate and homocysteine metabolism in neural plasticity see the review by Mattson and Shea (2003).

Deficiency of folate during pregnancy is associated with a greatly increased risk of neural tube defects whilst vitamin B₁₂ deficiency is associated with elevated fetal homocysteine levels and increases the incidence of CNS developmental defects. Deficiency during infancy may result in psychomotor retardation, sensory neuropathy, severe hypotonia, seizures and apathy, which may result from impaired methylation.

Careful assessment of patients presenting to physicians or haematologists with megaloblastic anaemia due to either folate or vitamin B₁₂ deficiency has shown that between half and two-thirds will have CNS complications responsive to appropriate vitamin-replacement therapy (Shorvon *et al.* 1980). These clinical manifestations have a considerable degree of overlap, although peripheral neuropathy and acute combined degeneration of the cord are seen more frequently with vitamin B₁₂ deficiency and depression with deficiency of folate. In one series of 24 patients admitted medically for severe folate deficiency, an organic brain syndrome including depression was present in 71% compared with 31% of controls (Reynolds 1973). Historical reports from the beginning of the twentieth century suggest that if left untreated all patients will go on to develop similar complications (Reynolds 1979).

Numerous studies over the last 40 years have shown a high incidence of folate deficiency in psychiatric patient groups, especially those with depression and in the mentally unwell elderly. Many of the earlier studies used serum folate levels, which are known to be lowered by a number of medications and by alcohol, though more recent studies using more reliable red-cell folate measurement have shown similar findings (Reynolds 2002). Carney *et al.* (1990) surveyed 285 consecutive patients seen in a psychiatric unit and found borderline (<200 µg/L) and definite (<150 µg/L) red cell folate deficiency in 31% and 12% of patients respectively. The levels in patients with depression were significantly lower than in other groups, but patients with alcohol dependency were also severely affected. The prevalence of folate deficiency in the elderly and results of studies suggesting an association between folate deficiency and cognitive decline are discussed in the section below.

In all such surveys it is hard to assess the causal significance of the low folate found. In the majority of cases deficient nutrition may have been responsible and, as with B₁₂ deficiency, this may often be secondary to the mental disorder itself. Should a causal relationship between folate deficiency and psychiatric disturbance exist it is also quite probable that this will impair food intake still further and establish a vicious circle. Regardless of direction of causality, several studies have shown that folate replacement is associated with a greater improvement in mental state (Carney & Sheffield 1970; Coppen *et al.* 1986). Godfrey *et al.* (1990) reported a double-blind placebo-controlled trial of adding methylfolate to standard psychotropic medication in 41 patients with low red cell folate, 24 with depression and 17 with schizophrenia. Methylfolate supplementation was associated with significant improvement in clinical outcome in both patient groups, which was more evident at 6 months than at 3 months. Subsequent studies have focused predominantly on the role of folate replacement in depression as discussed below.

Depression

The first reports of an association between folate deficiency and depression appeared in the 1960s with the development of reliable assays for folate (Alpert *et al.* 2000). Shorvon *et al.* (1980) examined the mental state of general medical patients presenting with megaloblastic anaemia due to either B₁₂ or folate deficiency and found depression to be the commonest disturbance, occurring in 50% of the low folate group compared with 20% of those with B₁₂ deficiency. Depressive symptoms have featured prominently in series of patients with folate deficiency associated with a number of different aetiologies, including malabsorption (Botez & Reynolds 1979), anticonvulsant-treated epilepsy (Edeh & Toone 1985), megaloblastic anaemia (Shorvon *et al.* 1980) and dietary restriction (Herbert 1961).

Conversely more than 20, mainly case-control, studies have shown low folate levels in patients with psychiatric disorders, especially those with depression (Alpert *et al.* 2000). Findings of the newer studies that use red blood cell folate assays, which are more indicative of intracellular stores, are generally comparable, showing that up to one-third of depressed patients have deficient or low folate levels (Carney *et al.* 1990; Godfrey *et al.* 1990; Bottiglieri *et al.* 2000). Bottiglieri *et al.* (2000) showed that this was invariably associated with evidence of functional deficiency, reflected by raised homocysteine levels. Furthermore, those with high plasma homocysteine had significantly lower concentrations of SAM and the monoamine metabolites of serotonin, dopamine and noradrenaline (i.e. 5-HIAA, homovanillic acid and 3-methoxy-4-hydroxyphenylglycol) in the CSF. There is also evidence to suggest that patients with depression who are also folate deficient may have more severe affective disorders and respond less well to conventional treatment

(Reynolds *et al.* 1970). Placebo-controlled trials have shown an improvement in mood at 4 months after treatment with 15 mg folic acid daily (Botez & Reynolds 1979) and double-blind placebo-controlled trials have shown improved affective morbidity after 1 year of 200 µg folic acid daily in patients with bipolar disorder treated with lithium (Coppen *et al.* 1986). Addition of 500 µg of folic acid to fluoxetine also significantly improved antidepressant response at 10 weeks in women in one study (Coppen & Bailey 2000).

However, population-based cross-sectional studies investigating the association between components of the one-carbon metabolic pathway and depression have found a much weaker association between depression and low folate. Bjelland *et al.* (2003) in a large study of nearly 6000 middle-aged and elderly subjects found no association of depression with either low folate or vitamin B₁₂, although hyperhomocysteinaemia (odds ratio 1.90) and the T/T MTHFR genotype (odds ratio 1.69) were both significantly associated. Tiemeier *et al.* (2002) in a large group of elderly subjects from Holland found only a mild non-significant association between depression and low serum folate, although a stronger association with vitamin B₁₂ deficiency and raised homocysteine was seen. Significant associations between depression and raised methylmalonic acid and non-significant association with low vitamin B₁₂ but not folate were also reported in findings from the Women's Health and Aging Study (Penninx *et al.* 2000). A recent Cochrane systematic review of the use of folate in depression concluded that the limited evidence suggests that folate may have a potential role as a supplement to other treatments for depression (Taylor *et al.* 2003).

Together these studies suggest that the association between folate and other components of the one-carbon metabolic pathway and depression are much more complicated than was previously thought. The observation that the MTHFR T/T genotype confers increased risk suggests that altered vitamin B status may be a risk factor for, rather than the result of, depression and signals the need for prospective and adequately sized double-blind studies. A causal relationship between folate deficiency and depression is also consistent with biogenic theories of affective disorder. Methylfolate is required for the synthesis of SAM which, as discussed earlier, is involved in numerous methylation reactions in the nervous system, including the synthesis of monoamines and other neurotransmitters. Moreover, SAM has been shown to have antidepressant properties of its own (Reynolds *et al.* 1984; Reynolds 1991).

Dementia

CSF folate levels are several times higher than in serum, suggesting that folic acid is likely to be important in cerebral metabolism. Occasional case reports have pointed to a close relationship between folic acid deficiency and organic psychiatric illness. Anand (1964) described a patient with

megaloblastic anaemia, myelopathy, impairment of memory and moderate dementia of 'frontal lobe type', who showed no response to B₁₂ but improved in all respects after starting folic acid. Read *et al.* (1965) similarly described an 82-year-old patient with megaloblastic anaemia due to nutritional deficiency in whom mental confusion and double incontinence improved with folic acid. Two further striking examples were provided by Strachan and Henderson (1967), both with advanced dementia. In each case the folate deficiency followed chronic malnutrition, and the dementia responded gradually to treatment with folic acid; there was a coincident megaloblastic anaemia in both cases but the blood picture returned to normal several months before the mental symptoms resolved. However, in view of the relative frequency of folate deficiency, especially in the elderly, these presentations with severe mental impairment appear to be a rare feature of folate deficiency (Melamed 1979).

Absolute or functional deficiency of folate has been shown to be quite a frequent finding in both healthy and mentally unwell elderly populations. In a case-control study in 164 patients with Alzheimer's disease, Clarke *et al.* (1998) found a significant association between raised homocysteine, low folate and vitamin B₁₂ levels and cognitive decline. A prospective population-based study in 370 healthy Swedish individuals over 75 years old showed that the presence of folate or vitamin B₁₂ deficiency doubled the risk of subsequently developing Alzheimer's disease (Wang *et al.* 2001). Meanwhile Reynolds *et al.* (1973) showed that among patients presenting in a general hospital with very low folate levels, cognitive abnormalities were significantly commoner than in controls, whilst a study in a community of healthy elderly subjects, many with folate levels within the normal range, folate levels correlated with measures of cognitive impairment (Goodwin *et al.* 1983). Similar considerations to those described above in non-elderly populations need to be borne in mind in the interpretation of these findings. Low folate levels have been found in association with depression, which may also be a precursor to cognitive decline; however, poor nutrition resulting from the disease process can also be found in both of these groups.

A recent UK population-based cross-sectional analysis of 3511 people over the age of 65 years showed that conventional folate deficiency (<5 nmol/L) or functional folate deficiency (serum folate <7 nmol/L and homocysteine >20 µmol/L) was present in 1 in 20 people aged between 65 and 74 years and in almost 1 in 10 of those aged over 75. Similar prevalences of vitamin B₁₂ deficiency were also found (Clarke *et al.* 2004). These authors highlight the association between low folate and raised homocysteine as a risk factor in ischaemic heart disease and stroke (Homocysteine Studies Collaboration 2002).

Schizophrenia and epilepsy

A small case-control study investigated homocysteine levels in folate-deficient patients with schizophrenia and normal

controls and showed that homocysteine levels were higher in schizophrenia (Susser *et al.* 1998). It has been argued that homocysteine may mediate the effects of folate and B₁₂ deficiencies in schizophrenia because elevated levels in this group are not always associated with conventional folate or B₁₂ deficiency. Genetic analyses have suggested that individuals with the C677T polymorphism in the gene encoding the MTHFR enzyme, which is present in 10–12% of the population and associated with a 70% reduction in enzyme activity leading to folate-resistant increase in homocysteine levels, contributes to cases of schizophrenia (Regland 1997). Clinical improvement with folate supplementation in schizophrenia has also been shown in a randomised placebo-controlled trial (Godfrey *et al.* 1990).

Laboratory work in animal models of epilepsy has shown that folates at high concentrations in the peripheral circulation or injected intraventricularly have excitatory properties and can induce seizures (Reynolds 2002). The recognition that a number of antiepileptic medications, such as phenytoin, primidone and phenobarbital, were associated with lowering of folate levels and folate-replacement therapy with reports of increased seizure frequency led to the suggestion that this antifolate effect may be responsible for their efficacy (Smith & Obbens 1979). Whilst it is now widely acknowledged that this is not the principal mechanism of action of these or other antiepileptic medications, evidence that folate may block or reverse γ -aminobutyric acid (GABA)-mediated inhibition may explain their observed excitatory properties (Reynolds 1991).

Treatment

Replacement with folic acid 5 mg three times daily should be implemented in the face of biochemically confirmed folate deficiency; lower doses (400 µg) are used for prophylaxis of neural tube defects in women wishing to become pregnant. However, replacement of folate should always be preceded by screening for B₁₂ deficiency, B₁₂ levels tend to fall when folic acid is started (Reynolds *et al.* 1971), and there is a risk of precipitating neurological disturbances by giving folic acid to patients with undiagnosed pernicious anaemia. There are no clear guidelines for the appropriate dose, formulation or duration of folate therapy for neuropsychiatric disorders associated with deficiency. Well-constructed, randomised, placebo-controlled trials will be needed before recommendations in this area can be made.

Electrolyte disturbances

A delicate balance must be maintained in the chemical environment, both intracellularly and extracellularly, to maintain the proper functioning of the CNS. With regard to this balance, certain relatively simple components have been identified: the correct acid-base balance, the proper gradient of sodium and potassium across the cell membrane, and the correct concentration of calcium, magnesium and

phosphate. These factors may be disturbed separately or together in many disease processes and mental symptoms may follow.

The metabolic dynamics involved in the production of mental symptoms are often complex, since disturbance of one aspect of electrolyte balance can have repercussions on others. Alterations in cerebral blood flow may follow and complicate the situation further. Nevertheless, the correct appreciation of the primary disturbance is of the utmost importance if appropriate treatment is to follow.

Electrolyte disturbance plays a prominent part in certain endocrine disorders and in uraemia. It complicates respiratory disorders and can assume great importance postoperatively or in other situations when patients are maintained on intravenous fluids for long periods of time.

Hypernatraemia

Hypernatraemia may develop from either excess water loss or decreased water intake, usually in the context of impaired consciousness, when the powerful thirst drive is impaired, or immobility. As serum osmolarity rises, water shifts from the intracellular to the extracellular spaces; therefore small increases in serum sodium or osmolarity reflect a large reduction in total body water. In environments of extreme heat, in fever, burns and conditions associated with hyperventilation, insensible water loss from the skin and lungs may reach several litres a day. Hypernatraemia will only develop if water replacement is unable to match these losses. The commonest cause of hypernatraemia is water loss through the kidneys, due to diuretics, osmotic diuresis or diabetes insipidus. ADH deficiency, excessive mineralocorticoid activity and rarely excess sodium intake (e.g. in the preparation of infant formula) are other causes of hypernatraemia. Sudden development of hypernatraemia may develop in acute pituitary failure.

In the context of preserved consciousness, hypernatraemia is associated with intense thirst. Hypernatraemia presents most commonly clinically in the very young or old and in those unable to express their needs due to impaired conscious level. Clinically, hypernatraemia is associated with dryness of the mouth, a greyish complexion and weight loss. The plasma sodium, chloride and urea tend to rise. Homeostatic brain mechanisms limit neuronal shrinkage by stimulating the synthesis of intracellular organic osmolytes, especially myoinositol, that serve to limit neuronal water efflux (Pasantes-Morales 1996). As water loss outstrips homeostatic mechanisms, patients develop increasing mental confusion and lethargy that gives way to delirium and coma (Swanson 1976). There is an increase in muscle tone. Brain shrinkage may be associated with tearing of bridging veins and hypernatraemia with venous thrombosis in the sagittal or other sinuses (Luttrell & Finberg 1959). Seizures may occur as a result of these complications (Bruck *et al.* 1968) or during rehydration, possibly as a result

of osmotic swelling of neurones. Central pontine myelinolysis is another complication associated with over-rapid rehydration.

The elderly are especially at risk in view of their narrow limits of physiological balance, diminished capacity for renal tubular absorption, and liability to chronic debilitating disease. Jana and Romano-Jana (1973) have described four cases of 'hypernatraemic psychosis' in which elderly patients were admitted to a psychiatric hospital in a confused and disorientated state.

Hyponatraemia

Hypotonic hyponatraemia is due to either primary water gain, with secondary sodium loss, or primary sodium depletion, with secondary water gain. Causes of primary sodium loss include:

- burns;
- prolonged sweating in tropical climates;
- gastrointestinal losses due to prolonged vomiting, fistulae, obstruction with tube drainage and diarrhoea;
- renal causes such as diuretics (especially thiazides), osmotic diuresis, Addison's disease, salt-wasting nephropathy and acute non-oliguric tubular necrosis.

The classic symptoms and signs of heat exhaustion include weakness, dizziness, pallor, profuse sweating, diminution of urine, rapid pulse and respiration, low blood pressure and cramping pains in the abdomen and limbs. The onset is usually sudden, and the response to sodium chloride by mouth is dramatic. However, the picture can be misleading when it sets in very gradually.

Primary water gain in the presence of normovolaemia is most commonly caused by SIADH. Common causes of SIADH are CNS disorders such as meningitis, encephalitis, haemorrhage, stroke, tumours or head injury; pulmonary diseases such as pneumonia, empyema, tuberculosis and carcinoma; malignant tumours especially those of lung, duodenum and pancreas; and pharmacological agents including hypoglycaemics, thiazide diuretics and psychotropics (see under Distinguishing primary polydipsia from diabetes insipidus, earlier). Adrenal insufficiency and hypothyroidism may also cause hyponatraemia. An important cause of primary water gain in psychiatric patients is compulsive water drinking, when water intake may overwhelm the renal excretory capacity (see also section cited above).

The clinical manifestations of hyponatraemia are principally neuropsychiatric, related to osmotic water shifts that lead to increased intracranial fluid volume and cerebral oedema. Symptoms depend on the rate of onset and the absolute serum sodium level, with symptoms much more likely to occur if hyponatraemia develops rapidly. Nausea, vomiting, anorexia and malaise are common early symptoms with marked lassitude and change of mood. With further reduction in sodium, headache, confusion and blurring of vision may occur, then impairment of consciousness, delirium and

coma. Muscle twitches and cramps are sometimes seen, and seizures, usually generalised, occur with sodium levels below 120 mmol/L (Price & Mesulam 1987).

Treatment consists of giving salt by mouth or, when necessary, intravenous saline. The administration of water alone or glucose in water can be dangerous, as the hypotonicity is aggravated further. Over-rapid correction of severe hyponatraemia risks causing central pontine myelinolysis. Retrospective studies have led to the recommendation that the rate of rise in serum sodium should be limited to <12 mmol/L in the first 24 hours and 25 mmol/L in the first 48 hours (Sterns *et al.* 1986); however even at these rates myelinolysis has been described (Karp 1995).

Hypokalaemia

Hypokalaemia may result from decreased intake, shift into cells or increased loss. A common cause is inadequate replacement in patients maintained for long periods on intravenous fluids. With the exception of chronic starvation and anorexia, and possibly the elderly on poor diets, diminished intake is seldom the sole cause, with the amount of K^+ in the diet almost always exceeding that excreted in the urine. Movement of K^+ intracellularly may transiently decrease serum K^+ and may be seen after myocardial infarction, in hypokalaemic periodic paralysis, and when diabetic ketosis is treated vigorously with insulin infusions. Increased loss may occur through the gastrointestinal tract or the kidneys. Gastrointestinal causes include hyperemesis gravidarum, chronic diarrhoea due to ulcerative colitis, malabsorption syndromes such as steatorrhoea, or via long-term laxative abuse. Renal causes include K^+ wasting associated with Cushing's disease and Conn's syndrome, the massive diuresis that may arise in diabetes mellitus, the diuretic phase following acute renal failure, and the rare Liddle's syndrome, in association with renal tubular acidosis and Bartter's syndrome. It may also result from the administration of diuretics, ACTH or adrenal steroids.

The clinical manifestations of hypokalaemia vary greatly between individuals and depend on the severity of hypokalaemia. Symptoms seldom develop until K^+ is less than 3 mmol/L. Fatigue, myalgia and proximal muscle weakness are common, although cranial nerve-innervated muscles are typically spared. More severe hypokalaemia is associated with progressive weakness and eventually complete flaccid paralysis. Smooth muscle may also be affected and presents with constipation, abdominal distention or paralytic ileus. Lethargy, apathy and depression, which can be profound in degree, are common accompaniments.

Apprehension and irritability are sometimes marked and an anxiety state may be simulated. Emotionally induced hyperventilation may be thought to be responsible for paraesthesiae, vague muscle discomfort and transient visual disturbances. Very occasionally a typical acute organic reac-

tion is seen, with disorientation, confusion, impairment of memory and delirium. In familial periodic paralysis emotional stress may precipitate an attack. Mitchell and Feldman (1968) report an example of a patient with renal tubular acidosis who was first thought to show a conversion disorder.

A woman of 30 complained of marked weakness of the arms and legs after a fall some hours earlier, and was unable to walk. There was a long previous history of anorexia, occasional vomiting, constipation and muscle spasms, and there had been several similar falls in preceding months. Marital difficulties were prominent and a conversion disorder was diagnosed. She slowly regained strength and was discharged after 4 days. One month later she was readmitted with extreme weakness of several hours' duration, and complained of sleeping excessively and frequent headaches. The serum potassium was low at 2.4 mmol/L but again spontaneous recovery occurred. Two days later there were similar complaints, the serum potassium was 1.8 mmol/L and the ECG showed typical changes. There had been no evidence of impairment of consciousness at any stage.

The ECG shows characteristic changes due to delayed ventricular repolarisation though these do not correlate well with plasma K^+ concentration. Early changes include flattening or inversion of the T wave, a prominent U wave, ST-segment depression and a prolonged QT interval.

Oral replacement with potassium chloride or bicarbonate is generally safest though nasogastric or intravenous infusion of potassium chloride may be needed if oral intake is impossible, and should be undertaken very cautiously. Normal saline is ideally used, as dextrose solutions promote insulin-mediated movement of K^+ into cells.

Hyperkalaemia

Potassium homeostasis is largely dependent on renal function and hence significant hyperkalaemia is mainly seen in renal failure. Severe Addisonian crises, acidosis, with or without insulin deficiency, and the use of drugs such as potassium-sparing diuretics and angiotensin-converting enzyme inhibitors are other associations. Cardiac toxicity precludes the appearance of nervous system manifestations in most cases, with bradycardia due to heart block, ventricular dysrhythmia or fibrillation and ultimately ventricular asystole (Riggs 1989). The most frequent neurological manifestation is diffuse muscle weakness and fatiguability akin to that seen with potassium depletion, which may rarely progress to a flaccid quadraparesis. This is most striking seen in association with Addison's disease.

Potassium channel antibody disorders

Diseases of potassium channels are caused by either autoantibodies against potassium channels or mutations in their encoding genes (Buckley 2005). Benign neonatal febrile convulsions, hereditary deafness syndromes, neuromyotonia, episodic ataxia, and intractable epilepsy have all been associated with mutations in voltage-gated potassium channels (VGKCs). The neurological syndromes associated with elevated potassium channel antibodies range from pure peripheral nerve hyperexcitability (PNH) to syndromes confined to the CNS such as limbic encephalitis. There can be varying degrees of CNS, autonomic and peripheral involvement.

The spectrum of PNH ranges from mild cramp fasciculation syndrome to more disabling neuromyotonia. In neuromyotonia there is muscle twitching and cramps, often associated with increased sweating. There may be sensory symptoms, especially dysaesthesia without numbness, which is probably a consequence of hyperexcitability of the sensory nerves (Buckley 2005). Occasionally, there is hand posturing resembling dystonia. On examination, there is visible myokymia (severe twitching) and muscle cramps often accompanied by muscle hypertrophy. Electromyography reveals fibrillations and fasciculation potentials at rest and a characteristic pattern of multiple responses to a single stimulus. The serum creatine kinase level may be elevated, and VGKC antibodies are elevated in 40% of patients. The clinical syndromes in patients with and without antibodies are indistinguishable. Hart *et al.* (2002) have classified PNH syndromes using the following characteristics:

- can be an isolated disorder or occur with CNS features;
- can be paraneoplastic, e.g. with thymomas;
- can be associated with other peripheral neuropathies or with other autoimmune diseases (e.g. myasthenia, systemic lupus erythematosus);
- can be non-immune-mediated (e.g. in motor neurone disease) or mediated by toxins or gold;
- can result from either gene mutations or other hereditary syndromes.

VGKC antibodies have also been identified in patients with non-paraneoplastic limbic encephalitis. Vincent *et al.* (2004) described 10 patients with limbic encephalitis associated with potassium channel antibodies, and Thieben *et al.* (2004) described seven such patients. These patients had a profound amnesic syndrome and were positive for potassium channel antibodies. On MRI, there was commonly signal alteration or atrophy in the medial temporal lobes bilaterally (8 of 10 cases in the Vincent *et al.* series). Only one of these patients had neuromyotonia (PNH), but epileptic seizures were common (6 of 7 cases in the Thieben *et al.* series). There was some evidence of improved cognition in these patients on treatment with steroids, plasma exchange and/or intravenous immunoglobulins.

Morvan (1890) described a syndrome of 'fibrillary chorea' that involved severe muscle twitching (myokymia), muscle pain and cramps, excessive sweating and disordered sleep. This syndrome has now been associated with the presence of VGKC antibodies, and the syndrome can now be used to describe a small group of patients with overlapping peripheral, autonomic and CNS involvement. For example, Liguori *et al.* (2001) described a 76-year-old man with peripheral muscle weakness and fasciculation. In the autonomic nervous system, he displayed sweating, itching, cardiac arrhythmias, weight loss, lacrimation, salivation, urinary incontinence and constipation. With respect to the CNS, there was confusion, memory impairment, visual and auditory hallucinations, and insomnia. Potassium channel antibodies were strongly positive. The sleep EEG was dominated by wakefulness, with only short (<1 minute) atypical rapid-eye-movement phases without spindles, K complexes or delta waves. The patient died 26 months after onset. These authors showed that the antibodies bound strongly to neuronal dendrites in rat hippocampus and thalamus. Lee *et al.* (1998) described a similar patient with a much better response to plasmapheresis, immunosuppression and thymectomy. Toosey *et al.* (2005) have recently reported a patient with similar peripheral and autonomic symptoms, but with a different pattern of CNS symptoms. This patient manifested severe frontal behavioural and neuropsychological changes, including confabulation, associated with corresponding hypometabolism on fluorodeoxyglucose-PET in the ventromedial frontal region.

Hypercalcaemia

The clinical manifestations of hypercalcaemia are described in the section on hyperparathyroidism (earlier in chapter). Severe hypercalcaemia is usually caused by malignancy or hyperparathyroidism. Sarcoidosis, adrenal insufficiency, thiazide administration, hyperthyroidism, vitamin D intoxication and milk-alkali syndrome (prolonged ingestion of calcium especially when taken as milk with an antacid) are other rarer causes. Solid tumours, especially squamous cell carcinoma of the lung and carcinomas of the breast and kidney with secondary bone deposits, multiple myeloma and lymphoma are the commonest associated malignancies. Hypercalcaemia associated with malignancy is often due to a combination of increased bone turnover secondary to high levels of tumourally produced parathyroid-related peptide and direct malignant destruction of bone by tumoral invasion (Waxman 1990). Long-term treatment with lithium may very occasionally produce hypercalcaemia by elevating the level of PTH (Christiansen *et al.* 1976).

The severity of symptoms depends on the serum calcium concentration and the associated medical conditions. Changes in mental status commonly occur with serum calcium above 14 mg/dL (3.2 mmol/L). Petersen (1968)

reported six examples, mostly due to vitamin D intoxication, with clinical pictures similar to those seen with hyperparathyroidism. Thirst, asthenia, depression and tension states were the main manifestations, and three showed acute organic psychoses. Weizman *et al.* (1979) reported that 7 of 12 patients with hypercalcaemia of malignancy had prominent psychiatric symptoms. Three showed depression or anxiety, sometimes severe, three developed acute organic reactions and one an acute paranoid psychosis. In all cases the mental symptoms disappeared within 2–6 days of serum calcium being restored to normal. Severe hypercalcaemia with impaired consciousness is more common in malignancy than hyperparathyroidism.

Hypocalcaemia

Hypocalcaemia may result from a deficiency of calcium or vitamin D in the diet, producing rickets in children and osteomalacia in adults. Hypoparathyroidism, acute pancreatitis, rhabdomyolysis and severe liver or renal disease are other possible causes. Anticonvulsant therapy is a cause of hypocalcaemia in patients with epilepsy. Acute severe forms are usually the sequelae of thyroid or parathyroid surgery, or arise as a complication of acute pancreatitis (Riggs 1989).

In children there is a characteristic triad of convulsions, laryngeal stridor and carpopedal spasm (see Hypoparathyroidism, Physical features, earlier). In adults the most important signs are those of neuromuscular irritability: increased deep tendon reflexes and positive Chvostek's and Trousseau's signs. Seizures are the main complication of acute severe hypocalcaemia and are more likely to occur in those with pre-existing epilepsy. Common psychiatric manifestations are described in the section on hypoparathyroidism (see Hypoparathyroidism).

Hypomagnesaemia

Magnesium is predominantly an intracellular ion with less than 10% in the extracellular space, and therefore low serum magnesium usually reflects a severe deficit in whole-body magnesium. Its presence in many foods makes deficiency in normal individuals rare. The most common causes of deficiency are severe protein calorie malnutrition, diabetic ketoacidosis, renal losses secondary to renal tubular necrosis (Hayes *et al.* 1979), sepsis, chronic alcohol dependency, in association with hypocalcaemia, and secondary to the use of drugs such as loop diuretics, aminoglycoside, cisplatin and ciclosporin that lower body stores. The main effects of low magnesium are on cellular membrane function. Calcium, potassium and chloride channel currents are modified and magnesium ions also reversibly occlude the ion channels associated with the excitatory NMDA glutamate receptor. In addition magnesium is involved in many enzyme systems, including those for intermediary metabolism, biosynthesis

of nucleic acids, proteins and lipids, and most systems that require adenosine triphosphate (Pappius 1976).

The clinical picture may be identical to that seen with hypocalcaemia, with hyperexcitability, muscle cramps, carpopedal spasm, tetany with Chvostek's and Trousseau's signs, hyperreflexia and seizures (Vallee *et al.* 1960). Serum calcium may be normal and parenteral magnesium sulphate promptly abolish the symptoms. Other clinical pictures that have been described include convulsions, depression, irritability, vertigo, ataxia and muscle weakness in the absence of tetany (Hanna *et al.* 1960); myoclonic jerks and bizarre multifocal seizures (Fishman 1965); tremors, fasciculation, chorea, athetoid movements, focal signs such as hemiparesis and aphasia, mild confusion and disorientation, delirium of sudden onset and stupor (Flink 1956; Hammarsten & Smith 1957; Randall *et al.* 1959; Hall 1973). All may be reversed by intramuscular or intravenous magnesium sulphate. In one study from the 1960s (Flink 1969) that would struggle to receive ethical committee approval today, volunteers were kept on magnesium-deficient diets for many months. Lethargy, tremors, fasciculations and spontaneous carpopedal spasms developed and all responded to magnesium replacement. However, all symptomatic subjects also developed secondary calcium depletion despite adequate intake and absorption, as well as hypokalaemia, making the specific contribution of magnesium deficiency alone difficult to determine.

Hypermagnesaemia

Clinically significant hypermagnesaemia is rare, mainly occurring as a result of excessive intake in the context of chronic renal failure. Case reports of hypermagnesaemia arising secondary to abuse of laxatives and/or antacids have also been described (Castelbaum *et al.* 1989).

Deep tendon reflexes are lost at lower serum magnesium levels before CNS depression develops, and neuromuscular paralysis may precede the clinical recognition of encephalopathy. Lethargy and confusion are common early manifestations (Alfrey *et al.* 1970) and may progress to areflexia, flaccid neuromuscular paralysis including facially innervated and respiratory muscles, parasympathetic paralysis and coma (Rizzo *et al.* 1993). This may mimic a brainstem stroke and serum magnesium levels should be measured in any patient with renal failure who develops encephalopathy with weakness and areflexia.

Serum magnesium levels have also been investigated in patients with schizophrenia (Kirov *et al.* 1994). Elevated magnesium has often been reported, but also lowered or normal levels, and the literature remains inconsistent (see Alexander & Jackson 1981 for a review).

Hypophosphataemia

Hypophosphataemia is defined as a serum phosphate of less than 0.83 mmol/L and severe hypophosphataemia as a

serum phosphate of less than 0.5 mmol/L. Like magnesium and potassium, phosphate is predominantly an intracellular cation, and low serum levels may not necessarily reflect low body stores. Most free phosphate is bound to calcium in bone. Its central role is in cellular energy and enzymatic processes, existing intracellularly predominantly as adenosine monophosphate, diphosphate and triphosphate (AMP, ADP, ATP) or as creatine phosphate. In hypoxia phosphate activates phosphofructokinase, the enzyme that controls glycolysis, and stimulates anaerobic metabolism.

Hypophosphataemia may arise from loss of total body phosphate or more commonly from shifts into the cellular compartment from the serum, a situation encountered in the treatment of diabetic ketoacidosis, when refeeding patients following a period of starvation, and in the management of chronic alcoholics (Territo & Tanaka 1973). In the latter case, hypophosphataemia may be at its worst 10 days after admission and the re-instigation of regular nutrition (Knochel 1977). Hypophosphataemia may affect all levels of the nervous system. The mechanism of CNS dysfunction is uncertain. Tissue hypoxia compounded by reduced cerebral blood flow due to decreased red cell 2,3-diphosphoglycerate may be causal, though in clinical practice coexisting disorders such as alcoholism and hypomagnesaemia make it difficult to determine the main factors involved.

Clinically, patients with hypophosphataemia may present with an acute confusional state with irritability and apprehension or with variable motor abnormalities including ataxia, athetosis, myoclonus, weakness, paralysis with loss of peripheral reflexes or a syndrome resembling Guillain-Barré. Lethargy, distal paraesthesiae, dysarthria and abnormal respiratory patterns may also be early features (Prins *et al.* 1973). A syndrome of impaired eye movements, confusion and ataxia resembling Wernicke's encephalopathy has also been described and hypophosphataemia should be considered in patients presenting with a clinical picture of Wernicke's who fail to respond to thiamine (Vanneste & Hage 1986). Reversible coma with and without seizures and cranial nerve areflexia and a reversible paralysis of movements resembling brain death have also been described (Young *et al.* 1982).

While replacing phosphate orally or if necessary parenterally, parenteral nutrition should be temporarily stopped until CNS symptoms resolve. If supplementation is required, milk that contains high levels of phosphate is advised. Magnesium supplementation should also be considered, as hypomagnesaemia will contribute to high urinary losses.

Low serum zinc

Zinc deficiency is rare but occurs in certain malnourished populations and in countries where bread with a high phytate content is consumed. It can be found with regional

enteritis and with malabsorption syndromes. The excretion of zinc is increased in liver disease, diabetes, some renal diseases and with certain drugs (Anon. 1973).

The syndrome most closely tied to low serum zinc is diminished acuity of taste and smell (hyposmia, hypogeusia), first described by Henkin *et al.* (1971) and shown to be responsive to the administration of oral zinc sulphate. Many such patients had developed the hypogeusia soon after a respiratory illness, while in others it appeared spontaneously. The strong perversions of taste and smell that were sometimes present could precipitate emotional disturbance including profound depression.

Henkin *et al.* (1975) monitored the low serum zinc produced by histidine in the treatment of six patients with progressive systemic sclerosis. The authors were able to follow the sequential appearance of anorexia, dysfunction of taste and smell, and ultimately the development of neurological and psychiatric features. The patients became dizzy and unsteady, with cerebellar symptoms in the form of ataxic gait and intention tremor. Several were irritable and easily upset, with depression and periods of weeping. Others showed memory impairments, lethargy, auditory and visual hallucinations and pronounced emotional lability. The disturbances correlated with the degree of lowering of serum zinc and with indicators of total body zinc loss. All were quickly reversed following the administration of zinc sulphate.

Staton *et al.* (1976) described a young male patient presenting with a picture resembling catatonic schizophrenia who responded rapidly to zinc administration after failing to respond to other treatments. He had presented with auditory and visual hallucinations, loose associations, blunted affect and disorientation in time and place. Drooling, negativism and catatonic postures became established. Phenothiazines were ineffective and led to severe extrapyramidal disturbance. After some months electroconvulsive therapy was tried and produced only transient improvement. A low serum zinc and high serum copper were discovered and oral zinc sulphate and pyridoxine were commenced. Thenceforward he made excellent progress and remained well 1 year later.

Acid-base disturbances

Systemic arterial pH is tightly maintained between 7.35 and 7.45 by buffering systems together with respiratory and renal regulatory mechanisms. Common clinical disturbances are simple acid-base disorders due to metabolic or respiratory causes; more rarely mixed pictures may develop.

Alkalosis

Metabolic alkalosis usually results from the loss of acid, most commonly as HCl due to repeated vomiting, or rarely from the ingestion of large quantities of sodium bicarbonate given, for example, in the treatment of peptic ulcer. Central and peripheral nervous system symptoms and signs such as apathy, delirium and stupor, a predisposition to seizures, paraesthesiae, muscular cramping and tetany occur that are similar to those of hypocalcaemia, because the proportion of ionised calcium is reduced even though the total serum calcium is normal.

An important cause of respiratory alkalosis from the psychiatric point of view is overbreathing. Attacks of hyperventilation are common in anxiety disorders especially at times of stress and in panic disorder. Hyperventilation also follows the ingestion of large quantities of salicylates.

The effects of respiratory alkalosis vary according to severity and duration but are primarily those of the underlying disease. Rapid decrease in P_{aCO_2} may cause dizziness, mental confusion and seizures even in the absence of hypoxaemia (Kasper & Harrison 2004). Experimental studies show that hyperventilation increases suggestibility and facilitates the induction of hypnosis. At an early stage perception is increased, but later dulled. As consciousness becomes impaired and awareness of the environment diminishes, the EEG begins to slow and high-voltage delta waves ultimately appear. Impairment of memory and calculation develop when the dominant frequency reaches 5 Hz. Psychological studies show impaired performance on tests of reaction time, manual coordination and word association, and there is often subsequent amnesia for events of the period (Wyke 1963).

When hyperventilation accompanies anxiety the emotional arousal is increased, creating a vicious circle. Paraesthesiae, circumoral numbness, chest wall tightness or pain, dizziness, inability to take an adequate breath and vertigo may themselves be sufficiently stressful to increase the patient's concern and reinforce the disorder. Mental confusion may become marked, and myoclonic jerks or epileptic phenomena may be precipitated. In severe cases the condition may progress to loss of consciousness.

It is uncertain whether these clinical phenomena depend directly on the lowering of carbon dioxide tension in the blood or on the rising pH and other metabolic changes in the neuronal environment. Reduced cerebral blood flow as a consequence of low P_{aCO_2} and vasoconstriction of cerebral arterioles may make a further contribution. The decrease in ionised calcium of the blood is almost certainly responsible for the tetanic phenomena.

Acidosis

Metabolic acidosis may result from an increase in endogenous acid production (e.g. lactate in lactic acidosis or

ketoacids in diabetes mellitus), loss of bicarbonate (as seen in hyperchloraemic acidosis associated with chronic diarrhoea) or accumulation of endogenous acids (in renal failure). Ingestion of exogenous acids (e.g. salicylates) produces a more complex picture associated with increased lactic acid production. The most prominent result is stimulation of the respiratory centre with deep and rapid respiration. Consciousness is progressively impaired and mental confusion or delirium is seen in varying degree. The precise clinical picture in the individual case is largely determined by the underlying condition and other associated metabolic derangements.

Respiratory acidosis (hypercapnia) provides a more distinctive clinical picture. Inhalation of 6–7% carbon dioxide can be shown to impair psychological functioning and lead to perseverative responses. In chronic respiratory disease mental dulling and drowsiness are common, and it is well known that if high-concentration oxygen is given to rapidly correct hypercapnia, respiratory drive can paradoxically be reduced further, precipitating mental confusion, irrational behaviour and impairing consciousness. Oxygen therapy should therefore be titrated carefully in chronic obstructive lung disease and chronic carbon dioxide retention.

Clinical features vary according to the severity and duration of the respiratory acidosis, the underlying disease and whether there is associated hypoxia. Chronic hypercapnia is associated with sleep disturbance, complaints of memory impairment, daytime somnolence, personality change, impairment of coordination, and motor disturbances including tremor, myoclonic jerks and asterixis (Kasper & Harrison 2004). Westlake *et al.* (1955) reviewed the clinical findings in carbon dioxide retention due to emphysema. Mental disturbances were usually present when the blood pH was below 7.2 or the P_{aCO_2} above 10.6 kPa, and ranged from mild impairment of consciousness, with irritability, disorientation and confusion, to delirium with auditory and visual hallucinations. Headache, muscle twitching and sweating were common accompaniments. When the pH fell below 7.1 or the P_{aCO_2} rose above 13.1 kPa, there was increasing lethargy and drowsiness leading ultimately to coma. Intracranial pressure was often raised, and papilloedema was sometimes seen. The disturbances were usually transient, because the pH is ultimately restored by renal activity, but in a minority of cases the outcome could be fatal.

The mental changes are thought to be due to the direct action of acidaemia or hypercapnia on the metabolism of cortical neurones. The rise of intracranial pressure is ascribed to the accompanying cerebral vasodilatation. The EEG shows delta waves, sometimes paroxysmal or episodic, at high arterial levels of carbon dioxide.

Uraemia

Uraemia may result from primary disease of the kidneys or from extrarenal causes. Any process resulting in prolonged

and severe reduction of renal blood flow may induce renal failure due to tubular epithelial damage, as may urinary tract obstruction at any point from the pelvic calyces to the urethra. Although the term 'uraemia' was originally adopted to reflect the belief that the syndrome was caused by the accumulation of urea and other end-products of metabolism, the true causes of the syndrome remain unknown. In addition to uraemia and other electrolyte disturbances, renal failure is associated with anaemia, malnutrition, impaired carbohydrate, fat and protein metabolism, and endocrine disturbances.

The severity of symptoms and signs of uraemia vary between individuals, depending on the severity of uraemia and the rapidity with which it has developed. It is typically more severe and progresses more rapidly in patients with acute deterioration in renal function (Locke *et al.* 1961). Early manifestations may be subtle (Stenbäck & Haapanen 1967), including drowsiness, apathy, insomnia and impaired concentration, and do not appear until the glomerular filtration rate has fallen to 20–35% of normal. Mild behavioural changes, impairment of memory and errors in judgement develop later, often in association with signs of neuromuscular irritability, hiccups, cramps and fasciculations and twitching of muscles.

A large series of patients seen in a renal unit reported CNS manifestations in 60%, rising to 75% when blood urea exceeded 18.0 mmol/L, with mental changes as common in patients with acute as well as chronic uraemia (Stenbäck & Haapanen 1967). Patients with uraemia usually present to physicians with physical symptoms, but very occasionally the mental changes can be the most prominent manifestation and lead directly to psychiatric consultation. This is more likely when uraemia has developed slowly. The picture may simulate neurasthenia with complaints of fatigue after mental effort or body weakness and exhaustion after minimal effort, muscular aches and pains, irritability, sleep disturbance and mood disturbance. Uraemia should always be considered in the differential diagnosis of delirium.

Sluggishness, memory impairment and sleep disturbance are not uncommonly seen in patients treated with renal replacement therapies. Psychometric studies have shown deficits in attention/response speed, learning and memory and perceptual coding in patients on both continuous ambulatory dialysis and haemodialysis.

Uraemic encephalopathy

Uraemic encephalopathy is an organic brain syndrome that occurs in untreated renal failure and in association with renal dialysis. The commonest mental disturbance is progressive torpor and drowsiness with the insidious development of intellectual impairment. The earliest symptoms may be subtle and include feeling generally unwell, fatigue, apathy and impaired concentration (Stenbäck & Haapanen 1967).

Difficulty with concentration is characteristically episodic: a patient may perform well for short periods of time but is unable to sustain mental activity.

With further progression the patient may become depressed or emotionally labile, memory becomes obviously impaired, and episodes of disorientation and confusion appear. Frontal lobe symptoms with impaired abstract thinking, listlessness and apathy prevail but anxious restlessness may also sometimes be seen. *Gegenhalten* (an involuntary, variable resistance to passive movement), grasp, palmomental and other frontal release signs also occur. In the later stages acute confusional states develop in one-third, with visual hallucinations, disorientation and agitation. Both the impairment of consciousness and the changes of mood fluctuate markedly, with lucid periods during which behaviour returns to normal. As in acute confusional states due to other causes the picture changes rapidly and paranoid developments are common.

Eventually more profound impairment of consciousness develops, with increasingly sluggish comprehension and reactions, slurring of speech, incontinence and ultimately coma. Seizures, usually generalised tonic-clonic though focal motor seizures are also common, develop in about one-third of cases. They are more frequent in acute than chronic uraemia and are usually a late feature. Meningism may be found in one-third and fascicular twitching, coarse postural and kinetic tremor, multifocal myoclonus and asterixis (a form of negative myoclonus) characterise later stages of the encephalopathy. Raised limb tone, hyperreflexia, ankle clonus and extensor plantar responses may also be seen in uraemic coma. Hemiparesis may occur in up to 45%, and curiously may exchange sides during the illness (Fraser & Arieff 1988). On recovery there is patchy or complete amnesia for the periods of disorientation and confusion.

Peripheral neurological manifestations

Neuropathy occurs in 70% of patients requiring renal replacement therapy, more commonly in men than women (Schaumburg *et al.* 1992). The neuropathy is distal, sensorimotor and predominantly axonal. Occasionally, intensely painful paraesthesiae may occur, typically in the feet or as band-like sensations (Mawdsley 1972). Weakness of dorsiflexion at the ankle is usually the first motor complaint. Nerve conduction studies may show an axonal pattern of impairment even before clinical signs appear. Isolated mononeuropathies are also common, particularly carpal tunnel syndrome. The most commonly affected cranial nerve is the vestibulocochlear (Burn & Bates 1998). The 'restless legs' syndrome (see Chapter 12) develops in a considerable proportion of patients, with or without overt neuropathy, presenting with unpleasant sensations in the lower limbs, worse in the evenings, which are relieved by movement (Raskin 1989). Renal replacement therapy or transplantation

usually improves the neuropathy, with sensory symptoms improving before motor and deep tendon reflexes recovering last. Further neurological manifestations include a myopathy, similar to that seen in hyperparathyroidism. For a comprehensive review, see Burn and Bates (1998).

Investigation of uraemic encephalopathy

Blood urea is raised and electrolyte disturbances including hyponatraemia, hyperphosphataemia, hypocalcaemia and hyperkalaemia are common. Anaemia is often marked in chronic renal failure. If performed, CSF analysis typically shows a mildly raised opening pressure and increased protein, although in aseptic meningitis up to 250 lymphocytes (250 mm³) and polymorphonuclear leucocytes and protein up to 1 g/L have been described (Madonick *et al.* 1950).

The EEG is usually most abnormal during the acute onset of encephalopathy (Burn & Bates 1998). There is generalised slowing, most marked frontally with an excess of delta and theta waves. In chronic renal failure the changes are less dramatic. They develop roughly in proportion to the severity of the clinical condition (Tyler 1968), with loss of well-developed alpha activity, progressive slowing, then disorganisation with runs of waves occurring at 5–7 Hz that ultimately replace all other activity. Bilateral spike-and-wave complexes in the absence of clinical seizure activity have been reported in up to 14% with chronic renal failure. On MRI, reversible T1 and T2 changes in the basal ganglia, periventricular white matter and internal capsule that resolve following dialysis have been described (Okada *et al.* 1991). However, CT or MRI are rarely useful in diagnosis though may help to exclude other causes of confusion such as subdural haematoma or hydrocephalus.

Gross lesions in the CNS are rare in the absence of marked hypertension. The most constant change is scattered neuronal degeneration, with chromatolysis and vacuolisation of nerve cells. In chronic cases this progresses to pyknosis and areas of cell loss.

Aetiology of mental disturbances

Although mental and neurological changes become commoner with increasing elevation of blood urea, it is widely accepted that urea cannot be responsible for all or even the majority of the symptoms. Considerable improvement can follow dialysis when urea is present in the dialysis fluid, and experimentally urea has not been found to have a strong neurotoxic effect. Other abnormalities must therefore play a direct aetiological role, with the level of blood urea serving mainly as an indicator of the severity of overall metabolic disturbance. Nevertheless, estimation of blood urea remains an important clinical indicator for monitoring the progress of the patient's condition.

The calcium content of the cerebral cortex is almost double that seen in normals, a change that may be mediated by increased PTH (Raskin 1989). In animal studies both EEG and brain calcium changes may be prevented by parathyroidectomy and in humans EEG and psychological abnormalities have been shown to improve after parathyroidectomy (Cogan *et al.* 1978).

In renal impairment the cerebral metabolic rate is reduced, with an associated decrease in cerebral oxygen consumption. These changes, which occur in the presence of normal levels of high-energy phosphates, have been attributed to a reduction in neurotransmission. Studies have suggested a reduction in the activity of the Na⁺/K⁺-ATPase pump, which is important in the release of neurotransmitters, especially noradrenaline and possibly also dopamine in renal failure (Minkoff *et al.* 1972; Fraser 1992). Endogenous opiates have also been investigated: circulating levels of β -endorphin are elevated in renal failure and there are reports of naloxone reversing encephalopathy in chronic renal failure (Mattana *et al.* 1993).

Arterial hypertension also contributes to the clinical picture, as verified by the pathological findings, causing transient neurological disturbances, fits and headache. In many cases a part is played by raised intracranial pressure, altered permeability of small blood vessels and anaemia. Erythropoietin therapy is associated with an improvement in cognitive function, with improvements in the speed and accuracy of information processing and an increase in the event-related P300 (Nissensohn 1989).

Other derivatives of protein such as uric acid may play a part, as may other toxins so far unidentified. Electrolyte disturbances are certainly important in many cases. Changes in sodium, potassium, calcium, chloride, phosphate, acid–base balance and osmolality can all be blamed in individual instances. The rapidity of the shifts appears to be the essential factor, whether this is in the direction of normality or abnormality (Tyler 1968).

Drugs have been strongly incriminated as a cause of mental disturbance in patients with chronic renal failure, accounting for over one-third of the episodes in some series (Richet & Vachon 1966; Richet *et al.* 1970). Sedatives and antibiotics appear to be mainly responsible, either by virtue of accumulation when the drug is excreted by the kidneys or as a result of increased susceptibility of the CNS in the uraemic patient.

Other causes of neuropsychiatric disturbance in patients with chronic renal failure also need to be considered. The risk of intracranial infection is increased in uraemia, especially when immunosuppressive drugs are used after renal transplantation; encephalitis due to herpes simplex or cytomegalovirus may be hard to diagnose in the prodromal stages, leading to behavioural disturbance and change of personality. Low-grade meningitis can lack the typical physical signs and present as depression with chronic headache.

The use of anticoagulants in maintenance haemodialysis may result in a subdural haematoma.

Dialysis-related disturbances

The psychological stresses associated with haemodialysis or transplantation bring a range of problems of their own. Salmons (1980) has reviewed the problems inherent in such management of chronic renal failure, with disruptions in work, daily life and family relationships. Not surprisingly there is a high incidence of depression, anxiety and disturbed sexual functioning among such patients. Short-lived psychotic episodes may be observed, usually in clear consciousness but often marked by 'organic' features such as visual hallucinations or loosely held delusions. Gradual improvement usually follows dialysis, with return of mental clarity a short while after chemical normality has been achieved. Occasionally, however, the time lag may be several days in duration.

Dialysis dysequilibrium syndrome

Dialysis dysequilibrium syndrome was first recognised in the 1960s when patients with uraemia were dialysed over shorter time periods, though with modern dialysis techniques severe forms are extremely rarely seen. It may occur during or after haemodialysis or peritoneal dialysis and is more common at the end of the dialysis session. In its mildest form it consists of restlessness, muscle cramps, nausea, fatigue and headaches. Symptoms generally subside over a few hours. A more severe form is characterised by myoclonus, confusion and seizures, sometimes progressing to coma with signs of brainstem compression (Peterson & Swanson 1964; Mawdsley 1972).

The syndrome is believed to develop because of the osmotic gradient that develops between the plasma and the brain during rapid dialysis. The more rapid clearance of urea and other osmotically active substances from the blood than from the CNS results in intracellular acidosis in the brain in association with an increase in organic acids. This results in an osmotic gradient that draws water into the brain parenchyma, producing encephalopathy, raised intracranial pressure and cerebral oedema. EEG carried out during dialysis shows changes consistent with such a hypothesis, these changes being reversible with hypertonic fructose infusion (Kennedy *et al.* 1963).

Dialysis encephalopathy (dialysis dementia)

Dialysis encephalopathy is seen in patients who have been on haemodialysis for many years and is characterised by a mixed speech dysarthria and dysphasia, myoclonus, dementia and eventually seizures and death. Following its description by Alfrey *et al.* (1972), it became recognised as one of the commonest causes of death in some units (Burks *et al.* 1976).

Fortunately, modifications to the dialysis procedure mean that it is now rarely seen.

A mixed dysarthria and dysphasia with dysgraphia during or immediately following dialysis was reported as the earliest clinical sign in the majority of patients. With time the language dysfunction became permanent and progressively more severe, myoclonic jerks were seen and patients became ataxic and dyspraxic. Paranoia, bizarre behaviour and episodes of delirium were sometimes prominent. Slow worsening of the disorder usually led to dementia, immobility then muteness and death. Treatment was ineffective and progression could continue despite restoration of normal renal function by transplantation.

Most patients developing the disorder had been on haemodialysis for several years. The aluminium content of the brain, especially the grey matter, was increased fourfold in uraemic patients dying from dialysis dementia compared with those dying from other causes (Alfrey *et al.* 1976; McDermott *et al.* 1978). This was at first ascribed to the aluminium in the phosphate-binding gels though it was later discovered that the regional incidence of encephalopathy in various centres correlated with the aluminium content of the water used as dialysate (Parkinson *et al.* 1979). Dialysis dementia should be considered in all patients on dialysis, and all forms of aluminium, especially aluminium-containing antacids and dialysate, should be withdrawn on the appearance of the symptoms described above. Desferrioxamine, an aluminium chelator, can safely be given long term and may reverse many of the features (Bolton & Young 1990).

Disturbances associated with renal transplantation

The increasing graft survival of renal transplants has led to a dramatic increase in the number of renal transplants performed, with an estimated 10000 carried out worldwide each year. Approximately 30% of transplant recipients develop neurological complications, which may result from direct side effects of immunosuppressive agents, rejection encephalopathy, CNS infections and post-transplant lymphoproliferative disorder. Emotional disorders are also frequently seen in this group, who are aware that their ongoing quality of life is determined by the future viability of their grafted kidney.

Acute porphyria

The porphyrias are a heterogeneous group of overproduction diseases resulting from genetically determined partial deficiencies in enzymes involved in haem biosynthesis. Their clinical manifestations are broad, leading Waldenström to describe porphyria as the 'little imitator' in contrast to syphilis 'the big imitator'. Three common subtypes of

porphyria give rise to neuropsychiatric disorders. Acute intermittent porphyria is the commonest form in the UK. It is inherited through an autosomal dominant gene on the long arm of chromosome 11, resulting in a 50% reduction of porphobilinogen (PBG) deaminase activity. Variegate porphyria, the other major form, is approximately one-third as common and is inherited through an autosomal dominant gene on the long arm of chromosome 1, resulting in reduction of protoporphyrinogen oxidase activity. It typically presents with light-sensitive erythematous or bullous skin lesions alone and is less commonly the cause of recurrent attacks, though it may also present in a similar manner to acute intermittent porphyria (Elder *et al.* 1997). The third acute form, hereditary coproporphyria, is the rarest and results from a deficit in coproporphyrinogen oxidase activity whose gene lies on chromosome 3. It presents with acute attacks and accompanying blistering skin lesions in approximately one-third. Plumboporphyria has only been described in a few cases but resembles acute intermittent porphyria clinically. Other conditions such as lead poisoning and hereditary tyrosinaemia may produce secondary abnormalities of porphyrin metabolism with similar clinical and biochemical findings.

Biochemical studies of relatives of patients with symptomatic acute intermittent porphyria suggest that at least 90% of individuals with acute intermittent porphyria or variegate porphyria are clinically latent. One study of blood donors showed inherited PBG deaminase deficiency in as many as 1 in 500 (Mustajoki *et al.* 1992). Predicting who will go on to develop clinical features has proven difficult, although women appear to be at greater risk than men (Hindmarsh 1993), with acute attacks approximately five times more common in women. Earlier uncontrolled studies had suggested an increased prevalence of PBG deaminase deficiency in psychiatric inpatients (Tishler *et al.* 1985) associated with agitated psychosis and apathetic or depressed withdrawal without neurological abnormalities. However, subsequent findings of a high prevalence of PBG deaminase deficiency in a non-clinical group suggest that this may be a non-specific finding.

The historical researches of MacAlpine and Hunter (1966, 1969) and MacAlpine *et al.* (1968) suggesting that George III's prolonged and puzzling mental illness may have been associated with acute porphyria drew public attention to these disorders, although considerable doubt has since been cast on some of these conclusions (Warren *et al.* 1996). The acute porphyrias have also been associated with the creative genius of Vincent van Gogh (Loftus & Arnold 1991) and with the obstetric history of Queen Anne (Phillips 1992). Acute porphyrias manifest clinically at any time from puberty onwards, most frequently during the second to fourth decades. As the disease exists so frequently in latent form, a family history may often not be forthcoming. Attacks may

take a myriad of forms that make diagnosis difficult. Failure to consider porphyria in the differential diagnosis may lead to the individual suffering multiple acute episodes before the diagnosis is finally made. Valuable reviews of the clinical features are provided by Crimlisk (1997) and Elder *et al.* (1997). Abdominal pain is almost universal, is severe, can occur in any quadrant and may also involve the back, buttocks and thighs. It is sometimes associated with guarding though not by true peritonism and may require large amounts of opioids for its control. Nausea, vomiting and constipation are common accompaniments. Tachycardia and hypertension are frequently described as features, though pulse and blood pressure may only be moderately raised and are of little diagnostic value. Autonomic neuropathy is responsible for many of the systemic manifestations, including abdominal pain, vomiting, constipation, hypertension and tachycardia. Abnormal cardiac reflexes have also been shown to occur during an attack though regress on remission (Laiwah *et al.* 1985).

Severe attacks can progress to a predominantly motor neuropathy, with weakness typically beginning in the proximal muscles, the arms more than the legs. Reflexes are usually diminished though extensor plantar responses can occur and Guillain-Barré syndrome and lead poisoning are important differential diagnoses. Sensory involvement, often with mild dysaesthesiae, occur in one-third often with bizarre distributions that sometimes raise the suspicion of a conversion disorder. Cranial nerve involvement, especially III, VII and X, may also occur. Seizures are seen in over 20% of cases, and status epilepticus may develop. Hyponatraemia, probably caused by SIADH, is also described (Kappas *et al.* 1989). Variegate porphyria presents with skin lesions alone in 75% in the UK, with the remainder split between mixed and neuropsychiatric features alone. Cutaneous features include photosensitivity, skin fragility, bullous lesions, facial hypertrichosis and hyperpigmentation.

'Mental symptoms' accompany attacks in 25–75% of cases and may dominate the clinical picture, although as many of the series have been undertaken by neurologists or physicians this is likely to be an underestimation (Crimlisk 1997). Emotional disturbances with anxiety, restlessness and depression often occur and may be persisting features (Patience *et al.* 1994; Kappas *et al.* 1995). Detailed psychiatric assessments have been limited to small series or case reports; psychotic features resembling schizophrenia with persecutory delusions, auditory hallucinations, social withdrawal and catatonia have been described (Tishler *et al.* 1985) as have affective symptoms with emotional lability, insomnia and grandiose delusions. Clouding of consciousness and confusion may progress to delirium, with hallucinations, delusions and disturbed behaviour. Coma sometimes develops abruptly. The occurrence of monthly luteal-phase attacks in women may lead to the false

diagnosis of an acute polymorphic psychotic reaction or a cycloid psychosis.

Precipitation of attacks

Drugs and the menstrual cycle are the most common precipitants of an acute attack (Kauppinen & Mustajoki 1992), though alcohol excess and inadequate malnutrition are also important precipitants. The current list of agents known to precipitate an acute attack is long and the *British National Formulary* or the Cardiff Porphyria Research Group should be consulted before a drug that is not known to be safe is prescribed. Notorious precipitants include antibiotics such as the sulphonamides and erythromycin; sedatives such as barbiturates, benzodiazepines and sulpiride; hormone products such as the oral contraceptive pill, anabolic steroids, hormone-replacement therapy and tamoxifen; antiepileptics such as phenytoin and carbamazepine; drugs of abuse including cocaine and amphetamines; as well as many commonly prescribed drugs such as antihistamines, diuretics, baclofen, metoclopramide, many of the tricyclic antidepressants and diclofenac. Importantly, many of the drugs that would be considered for use in the mental state disturbances commonly seen in acute porphyric attacks have been associated with their precipitation, necessitating considerable care in the use of the agents. Of the antipsychotics chlorpromazine appears the safest, and there are few data on the atypicals. There are no data on amisulpride though sulpiride is associated with precipitating attacks so it should probably be avoided. There are a few case reports describing the uncomplicated use of olanzapine and cell culture studies have suggested that it may be safe. Mixed reports have been associated with risperidone use and there are currently no data on the use of quetiapine or zotepine; clozapine is believed to be safe. Of the antidepressants, most of the tricyclics should be avoided, but fluoxetine and paroxetine appear to be safe though there are currently too few data to comment on the use of the newer agents, mirtazapine, reboxetine or venlafaxine. The above resources should be consulted before the use of any of these newer agents is contemplated. Other drugs judged safe include aspirin, narcotic analgesics, penicillin, streptomycin, tetracycline, propranolol, paraldehyde and probably clomethiazole (Moore & Disler 1988; Kappas *et al.* 1989; McColl *et al.* 1996).

The importance of nutrition is shown by attacks that occur while on reducing diets, especially when these lead to precipitous loss of weight, and cases have been described of attacks occurring after missing several meals (Kappas *et al.* 1989). The mechanism by which starvation may trigger an attack is uncertain, though a rise in urinary excretion of aminolaevulinic acid (ALA) and PBG has been described with calorie restriction, and is reversed by increased carbohydrate intake (Welland *et al.* 1964). Oestrogen and proges-

terone aggravate porphyria (Welland *et al.* 1964) and cyclic attacks most commonly occur in the luteal phase, associated with high hormonal levels, and decline after the menopause. Previous claims that stress, surgery and infection are precipitants have not been supported by published data.

Investigations

Most difficulties in the diagnosis of the acute attack occur in patients without a family history of porphyria, especially if the combination of symptoms is atypical. Increased urinary excretion of PBG confirms the diagnosis of an acute attack, which is also associated with increased urinary excretion of ALA. Screening tests using Ehrlich's reagent lack sensitivity and may produce false-positive results; although of use in an emergency situation, they should always be confirmed with quantitative assay. Porphyrins are very light sensitive and break down quickly under normal conditions so urinary samples should be stored in the dark and transported to the laboratory as soon as possible. A negative result does not exclude an acute attack since some patients fail to hyperexcrete. If clinical suspicion persists, quantification of PBG and measurement of faecal and plasma porphyrins is essential. This is especially true in variegate porphyria and hereditary coproporphyria where excretion of PBG may fall below the detection level of most assays very soon after symptom onset. Caution is also required on account of the false-positive results that can occur in the urine with certain febrile illnesses, in lead poisoning and in patients receiving phenothiazine drugs (Reio & Wetterberg 1969).

The EEG often shows abnormalities during acute attacks, with slowing of dominant frequencies and an excess of intermediate slow activity. Sometimes, however, it remains entirely normal. Isolated records are therefore of little help in the diagnosis, but serial recordings can occasionally be useful in confirming the organic origin of symptoms in attacks of uncertain nature. A number of case reports have described MRI and other imaging changes in acute attacks, with multifocal cortical and subcortical lesions that resolve with resolution of the attack (King & Bragdon 1991; Aggarwal *et al.* 1994; Kupferschmidt *et al.* 1995; Utz *et al.* 2001). Some have hypothesised a vascular aetiology for these changes in view of their mild enhancement with contrast, rapid resolution following treatment of the attack and similarity to the lesion distribution seen in hypertensive encephalopathy. A report using conventional angiography has also demonstrated cranial vasospasm. Pathological studies of peripheral nerves show a predominantly motor axonal neuropathy with secondary Schwann cell reactions, findings consistent with PBG-deficient mouse models. These studies have suggested that rather than ALA being directly neurotoxic, the axonopathy is likely to be caused by local deficiency of haem-containing

proteins such as the mitochondrial cytochromes (Meyer *et al.* 1998; Lindberg *et al.* 1999).

Differential diagnosis

Porphyria is notorious for leading to mistakes in diagnosis, and patients are sometimes admitted repeatedly to psychiatric units before the condition is discovered. An impression of psychiatric illness is reinforced by the patient's emotional instability during attacks, and the long history of intermittent physical complaints for which no cause has previously emerged. Diagnoses of personality disorder or an anxiety, somatisation or conversion disorder are commonly made when the patient complains of weakness of the limbs and varied aches and pains unbacked by physical signs. Psychotic developments may likewise obscure other aspects of the disorder and lead to a primary diagnosis of depressive illness or acute schizophrenia. Other patients are admitted to general medical wards with suspected appendicitis on account of abdominal pain and vomiting. Intestinal obstruction may be diagnosed when there is severe constipation. Other cases may be mistaken for Guillain-Barré syndrome, or the combination of fits and hypertension may suggest hypertensive encephalopathy.

Treatment and outcome

The chief aim should be prevention of attacks by advising the patient on drugs which must be avoided and about the importance of adequate nutritional intake. Abstention from alcohol should be advised, particularly whisky and red wine, though studies in specialist centres have shown that 87% of patients with inducible porphyria continue to drink alcohol (Thunell *et al.* 1992). It seems prudent to advise early consultation and rapid treatment for concurrent intercurrent infections. On occasion the onset of an attack can be aborted by increasing carbohydrate intake. In women with attacks related to menstruation, suppressing ovulation with a luteinising hormone-releasing hormone analogue has been shown to reduce the number of attacks (Herrick *et al.* 1990).

The symptomatic treatment of the acute attack is described by Thadani *et al.* (2000). For severe pain, opioids are safe and pethidine, morphine or diamorphine may be given. Sympathetic overactivity may be treated with propranolol. Seizures may be related to hyponatraemia so electrolytes should be monitored regularly and fluid restriction used if hyponatraemia develops. If an antiepileptic is required, the newer agents vigabatrin and gabapentin have been shown to be safe. The drugs of choice for emotional disturbance are chlorpromazine, promazine or trifluoperazine. Oral and intravenous glucose to maintain a high-energy intake and intravenous haem arginate are the mainstays of treatment, which by reducing the synthesis of ALA results in biochemical and clinical remission. Recently tin protoporphyrin, an

inhibitor of haem oxygenase, has been shown to prolong remission when given with haem arginate (Dover *et al.* 1993), although side effects of cutaneous photosensitivity and potential toxicity currently limit its use.

The duration of attacks varies widely from a few days to several months. The majority subside completely without enduring defects. Some patients, however, are left severely crippled with weakness or muscular wasting, and some remain psychotic for long periods of time. Ultimately there is usually full physical and mental recovery.

Klinefelter's syndrome and other sex chromosome aneuploidies

Klinefelter's syndrome (KS) results from the presence of one or more additional X chromosomes in the nucleus of the male. It is the most common of the sex chromosome aneuploidies with a prevalence of approximately 1 in 800 males (Hook 1992). Diagnosis is often not made until puberty or early adulthood when it often presents with delayed sexual maturation or infertility. As originally described, the typical 47XXY phenotype is characterised by small firm testes, infertility with azoospermia, impaired sexual maturation, gynaecomastia and elevated gonadotrophins (Klinefelter *et al.* 1942). Other clinical manifestations may vary depending on the extent of androgen deficiency and include features of eunuchoidism (long legs and wide span, decreased or absent facial, axillary and pubic hair, gynaecomastia, female fat distribution and small testes and penis). Subsequent reports have expanded the clinical phenotype in recognition of associated cognitive, language and behavioural abnormalities (Simpson *et al.* 2003).

Treatment with testosterone replacement from early puberty has been recommended and shown to improve mood and concentration in addition to its virilising effects (Nielsen *et al.* 1988). A high prevalence of psychiatric disorder in KS and the other sex chromosome aneuploidies (47XXX, 48XXXY, 48XXYY, 49XXXXY) and the growing recognition of focal cognitive deficits have been the twin focuses of psychiatric interest in this condition.

Cognitive and language deficits

Early reports of an excess of KS among patients in hospitals for the learning disabled led to the view that severe impairment of intellect was characteristic. However, subsequent case studies and findings from prospective cohort studies begun in the early 1970s to determine the incidence of sex chromosome aneuploidies have suggested that delayed language development with only mildly reduced full-scale IQ are more characteristic of boys with KS (Leonard *et al.* 1979; Walzer *et al.* 1982; Bender *et al.* 1987). The degree of intellectual impairment is proportional to the number of additional X chromosomes, with an approximately 15-point reduction

in IQ with each additional chromosome (Simpson *et al.* 2003). More detailed psychometric studies have shown a differential impairment in cognitive functions, with impaired verbal compared with non-verbal abilities in children with KS. Thus Netley and Rovet (1982) found mean verbal and performance WISC IQs of 85 and 101, respectively, in their sample of 33 children with XXY karyotypes. Though still within the normal range, the verbal IQ was significantly lower than performance IQ and verbal IQ in unaffected sibling controls.

From an early age, boys with KS show language problems reflecting delayed language acquisition (Leonard *et al.* 1979) and poor skills in sentence building, intonation and word naming. At a later age they show poorer articulation and comprehension and difficulties with verbal abstraction, syntax production and word finding (Walzer *et al.* 1982). Graham *et al.* (1988) suggested that these problems reflect a more fundamental impairment with accessing, retrieving and applying linguistic information. Rovet *et al.* (1996) reviewed the literature and hypothesised that KS deficits are primarily language based and may stem from an underlying impairment in auditory temporal processing and working memory. Evidence of frontal executive deficits are conflicting, although Temple and Sanfilippo (2003) have recently suggested a specific impairment in inhibitory skills. Spatial abilities and spatial processing speed appear to be spared (Walzer *et al.* 1978; Bender *et al.* 1986). In many respects this pattern of deficits is the reverse of that found in subjects with Turner's syndrome (see following section).

Considerable debate surrounds the relative influence of genetic and hormonal influences on the cognitive profile seen, although there have been few studies comparing adult with childhood cognitive profiles or even comparing testosterone-treated with untreated boys. Boone *et al.* (2001) have suggested that the characteristic cognitive profile seen in boys with KS changes as they mature, with a reduction in performance IQ and associated increase in verbal IQ occurring after adolescence. They argue for an early left hemisphere dysfunction related to developmental slowing in the rate of cell division prenatally followed by right hemisphere disturbance appearing in a subgroup in young adulthood due to a combination of low testosterone and high oestrogen levels. Imaging studies have recently begun to address this problem. Warwick *et al.* (1999) showed a reduction in whole-brain volume in KS with bilaterally enlarged ventricles, whilst Patwardhan *et al.* (2000) showed a reduction of left temporal lobe grey matter consistent with the observed verbal and language deficits and showed that relative preservation of grey matter in the left temporal region was associated with exogenous testosterone during development. Interestingly, testosterone supplementation was also associated with increased verbal fluency scores in this study. Other brain abnormalities have been described in KS: a high prevalence of EEG abnormalities has been reported, chiefly slowed

alpha but also slow-wave dysrhythmias and paroxysmal features (Hambert & Frey 1964). Epilepsy is also commoner than chance expectation.

Psychiatric features

A high prevalence of psychiatric disorder has emerged in this condition. Personality and behaviour may be abnormal and there is a probable excess of psychotic illness. Some psychiatric features appear to be attributable to the endocrine disorder, others to be more directly related to the chromosomal abnormality.

The personality in patients with KS is sometimes abnormal. A variety of pictures has been described, ranging from markedly antisocial conduct to passivity and social withdrawal. Common descriptions are of patients lacking in drive and initiative, with severe restriction of interests and generally indolent, insecure and dependent. At the same time tolerance of frustration tends to be impaired, with explosive irritability and outbursts of aggression. Poor school and work records, marital instability and impoverished social relationships are said to be common.

Nielsen's (1969) review showed histories of alcoholism in 6% and of criminal behaviour in 12% of patients. A small excess of XXY patients has been reported in surveys of institutions caring for severely disturbed criminals, along with the more usual excess of XYY or XYYY karyotypes (Swanson & Stipes 1969). However, Schiavi *et al.* (1984) failed to support any excess of violent or aggressive behaviour among Klinefelter (or XYY) subjects in their comprehensive survey from Copenhagen. The prevalence of criminal convictions was slightly higher than for XY men, but this difference disappeared on controlling for intelligence and parental socioeconomic status. Moreover, the great majority of the offences committed did not involve personal violence.

The endocrine disorder may play a part in hindering personality maturation and contributing to some aspects of personality difficulties. Thus patients with hypogonadism due to other causes are typically shy, timid and markedly lacking in drive. However, they tend to show more stable histories and temperaments than patients with KS, and lack any excess of criminal behaviours. Wakeling (1972) compared 11 patients with KS and nine other hypogonadal patients seen in a psychiatric hospital; both groups showed insecurity and low tolerance of frustration, but passivity was more marked in the hypogonadal patients and impulsive erratic behaviour in the Klinefelter patients. The latter, moreover, frequently had histories of prepubertal maladjustment, with a higher incidence of unsettled schooling, neurosis and behaviour disorder in childhood. It appears, therefore, that in KS delayed cerebral maturation may make a contribution, over and above the androgen deficiency, in leading to poor social adjustment and disturbed personality functioning.

Sexual problems, as might be expected, are not uncommon. Potency tends to be low and to show an early decline, especially when features of hypogonadism are marked (Pasqualini *et al.* 1957). Androgen treatment can be successful in restoring libido and potency (Beumont *et al.* 1972). Occasional reports have described transvestism, exhibitionism and paedophilia in patients with KS, although there is little to suggest that these are over-represented in the syndrome (Orwin *et al.* 1974). Sexual pathology, when it occurs, probably again reflects the restricted personality development and incapacity for deep interpersonal relationships. The more extreme examples of deviant sexual practice have usually occurred in severely antisocial or psychotic individuals.

Mental hospital surveys, reviewed by Forssman (1970), have indicated a threefold increase in patients with KS compared with the general population. This appears to be due mainly to psychotic illnesses of a schizophrenic nature. Nielsen (1969) found that 6% of patients recorded in the psychiatric literature had been given a diagnosis of schizophrenia, and another 7% had psychoses of an uncertain type but almost all with paranoid delusions. Well-documented examples of schizophrenia in association with KS are provided by Pomeroy (1980) and Roy (1981). The increased risk of mental illness may represent another facet of the increased vulnerability to stress of the patient with KS, or may have more direct genetic determinants.

There is little to suggest an increased incidence of organic psychiatric illness. Jablensky *et al.* (1970) have described a patient who demented rapidly in his early forties, showing diffuse white matter degeneration and adrenal cortical atrophy at autopsy; however, this may well have represented a chance association with KS.

Turner's syndrome

The XO karyotype is characterised by primary amenorrhoea with streak ovaries and consequent sexual infantilism, short stature and multiple congenital abnormalities. Somatic anomalies primarily affect the skeleton and connective tissue and include short stature, webbed neck, low hairline, cubitus valgus—wide carrying angle, oedema of hands and feet, nail dysplasia, and widely spaced nipples with a 'shield'-like chest. Facial appearance is often characteristic, with a small jaw, fish-like mouth and low-set ears. Congenital lymphoedema and poor development of the lymphatic channels is believed to be responsible for many of the characteristic phenotypic changes and may also be responsible for coarctation of the aorta. Other systems commonly involved include the cardiovascular system (bicuspid aortic valve in 50%, coarctation of the aorta in up to 20% and frequent hypertension), the urinary system (horseshoe and other structural abnormalities of the kidneys) and endocrine system (primary hypothyroidism in up to 50% and glucose intolerance is

common). The classic 45 XO karyotype is seen in half, with the remainder made up of mosaicism, isochromosomes of X, ring or partial deletions of the X chromosome (Jacobs *et al.* 1990). Treatment is frequently with growth hormone, and with oestrogen from adolescence.

Psychiatric interest in the condition has largely centred on the cognitive functioning of such patients. Money (1963, 1964) drew attention to the common finding of a lower performance than verbal IQ paralleled by inferior scores on tests of perceptual organisation when compared with scores on verbal comprehension, discrepancies that became more marked at the higher intelligence levels. Subsequent investigation has identified specific deficits in visuospatial and visuo-perceptual abilities (Pennington *et al.* 1985), motor function, non-verbal memory, executive function and attentional abilities (Ross *et al.* 2002). Finer-grained analysis of the language of women with Turner's syndrome has also led to the identification of subtle speech difficulties, in particular reduced oral fluency and abnormal narrative production (Temple 2002). Calculation difficulties (Bruandet *et al.* 2004) and deficiencies in social cognition hypothesised to correlate with previously identified personality characteristics have also been described (Lawrence *et al.* 2003a).

It remains uncertain how far the specific cognitive deficits and difficulties in social functioning seen in girls with Turner's syndrome reflect the direct effects of genes on cerebral maturation or reflect more indirect consequences of hormonal deficiencies resulting from the genetic defect. Ross *et al.* (2002) assessed the neurocognitive profile of 71 adult women with Turner's syndrome who were treated with oestrogen replacement including 10 who had apparently normal ovarian function. As with girls with Turner's syndrome, the adult women continued to show impairment on visuomotor tasks with a spatial component, tasks involving the manipulation of spatial-relational information, and attention tasks requiring control of impulsivity and self-monitoring. Conversely, motor speed and verbal memory in tasks without heavy spatial loading have previously been shown to be oestrogen responsive (Ross *et al.* 2000). They argue that the lack of responsivity of the core cognitive deficit seen in Turner's syndrome to oestrogen replacement, noted even in the 10 women with apparently normal ovarian function, points towards a genetic aetiology. This would be consistent with Murphy *et al.* (1994) who showed that visuospatial ability was negatively correlated with the percentage of lymphocytes containing the XO karyotype in a subset of patients with XO mosaicism. Whilst there is little direct evidence to suggest that the neurocognitive deficits are due to absence of fetal exposure to sex hormones, the identification of steroid receptors in several areas of the primate brain during prenatal and postnatal development and the correlation between periods of early steroid production and periods of rapid brain growth suggest a role for sex hormones in early brain development (Brinton *et al.* 1997).

Structural and functional imaging studies have identified a number of abnormalities in cortical and subcortical brain regions in women with Turner's syndrome. Murphy *et al.* (1993) showed that patients with Turner's syndrome showed significantly smaller cerebral hemisphere volumes, parieto-occipital brain matter volumes, and smaller hippocampi, lenticular nuclei and thalamic nuclei bilaterally. On many of these measures the mosaic patients occupied an intermediate position. Among the group as a whole there was significant right-left asymmetry in parieto-occipital brain matter volumes, that on the right being reduced. Subsequent studies have replicated the parieto-occipital volumetric reduction and functional studies have shown complementary reduction in metabolic activity (Reiss *et al.* 1995; Murphy *et al.* 1997). This decrease in parietal lobe grey matter is consistent with the broad impairment in visuospatial skills described as the core neuropsychological deficit in Turner's syndrome (Brown *et al.* 2002).

Clinical series have frequently found that girls with Turner's syndrome are more immature and have weaker social relationships, school performance and self-esteem than matched controls (Kihlbom 1969; McCauley *et al.* 1995). These difficulties are common and typically worsen at adolescence but rarely progress to frank psychopathology or developmental delay (McCauley *et al.* 1995). Observations have shown that girls with Turner's syndrome make less eye contact during social interactions and have greater difficulties interpreting non-verbal communication (Lawrence *et al.* 2003b). Using a specially developed social cognition questionnaire sensitive to flexibility and responsiveness in social interactions, Skuse *et al.* (1997) showed that quality of social interaction was dependent on whether the X chromosome was maternally (Xm) or paternally (Xp) inherited. Girls with a paternally inherited Xp chromosome were significantly better adjusted, with superior verbal and higher-order executive function skills that mediate social interactions. The same group has further shown that women with maternally inherited Xm chromosome also have impaired facial recognition and are impaired at recognising emotions, especially fear in the faces of others (Lawrence *et al.* 2003b). Also described are impairments in reading intentions and emotions from the eyes, an important component in the development of social cognition that has been shown to be impaired in individuals with autistic spectrum disorders. Together this evidence suggests a role for X expression in relation to the development of sociocognitive abilities and the possibility of an X-linked locus that underlies the development of sexual dimorphism in social behaviour.

Addictive and Toxic Disorders

Mayur Bodani,¹ Laurence J. Reed² and Michael D. Kopelman²

¹West Kent Neurorehabilitation Unit, Sevenoaks Hospital, Kent

²Institute of Psychiatry, King's College, London

This chapter is divided into two parts, the first reflecting nervous system toxicity deriving from intentional exposure to addictive substances with implicit yet unintended toxicity (addictive disorders) and the second relating to those disorders arising from incidental exposure to environmental toxins (toxic disorders).

A variety of lines of evidence from animal behavioural research and functional imaging show that a diverse group of substances share distinct reinforcing or 'rewarding' properties. These substances act to alter the function of a common set of neurobiological substrates to produce the compulsive behaviours characterised as addiction. Following a general consideration of the complex processes underpinning addiction, we consider the disorders specific to alcohol, licit and illicit drugs with psychoactive properties and abuse potential in succession.

Non-addictive drugs, certain metals and chemicals are the exogenous toxins that are considered later in this chapter. The effects of toxins derived from invading microorganisms have been briefly considered in Chapter 7 and the toxic products of disordered metabolism in uraemia and hepatic dysfunction in Chapter 10. Poisoning due to metals and other chemical compounds is largely the province of industrial medicine, but must also be borne in mind in occasional patients who present with psychiatric illness of uncertain aetiology.

ADDICTIVE DISORDERS

Addictive disorders have not been separately addressed in previous editions of this book, perhaps reflecting the difficulties in considering addiction as a 'brain disease', the complexity of the disorder as manifested with respect to the variety of substances with abuse liability and, lastly, the competing view of addiction as a moral disorder. Indeed,

Hyman (2007) in a very recent review points out the considerable difficulties in considering such a common yet remarkable condition as addiction as a 'brain disorder' with all the attendant implications for responsibility, voluntary behaviour and free will. That difficulty aside, the disease model of addiction has considerably advanced our understanding of the condition, factors predisposing to its development and its consequences. The earliest coherent consideration of the disease model of addictive disorders was addressed by Himmelsbach (1943) who expressed the view that the disorder required the presence of a physical abstinence syndrome, and that the state of dependence reflected an acquired abnormal state wherein increasing amounts of the substance were required to maintain physiological equilibrium. Clear difficulties arise with such a definition in that, following a period of physiological dependence, the compulsive behaviours are exacerbated rather than lost, requiring definition of a further term 'psychological dependence' (Eddy *et al.* 1965), again a label that has proved rather unhelpful. Currently, modern diagnostic thought is concentrating on a more precise definition of addiction for the forthcoming *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-V, focusing on compulsive behaviours and marking a distinction from the DSM-IV criteria for substance dependence *per se* (O'Brien *et al.* 2006).

Koob and Le Moal (1997) have defined drug addiction as a state characterised by (i) a compulsion to seek and take the drug, (ii) a loss of control in limiting intake and (iii) the emergence of negative emotional states (e.g. dysphoria, anxiety, irritability) when access to the drug is prevented. They proposed that the condition arises from the acquisition of unstable 'allostatic' adaptations to specific stress, emotional and reward pathways – hedonic homeostatic dysregulation. Important competing theories, seeking to provide a more complete inclusion of phenomena observed in addiction,

Fig. 11.1 Key elements of the neurocircuitry of addiction (see also Plate 11.1). (From Koob *et al.* 2008 with permission.)

include the incentive–salience model (Robinson & Berridge 1993), wherein neural circuits underpinning the importance or salience of stimuli are sensitised by repeated psycho-stimulant exposure, leading to compulsive behaviours. This particular theory has the advantage of divorcing the dopaminergic system from function as simple ‘reward’ system. Everitt and Robbins (2005) have focused on the reinforcement of drug responses related to learning and memory in the transition from episodic ‘impulsive’ to addictive ‘compulsive’ drug-taking behaviours. This model emphasises the multiplicity of basic neural systems underpinning addictive behaviours (Fig. 11.1: see also Plate 11.1) (Koob *et al.* 2008). Lastly, a more ‘cognitive’ view of addictive behaviours has been emphasised by Bechara (2005), positing impairment of prefrontal cortical functions monitoring internal state and guiding future actions as the basis for maladaptive drug-taking. Possibly this works through impaired inhibition of impulsive behaviours, although this latter model may better explain vulnerability to addiction rather than the state itself. Neuroimaging using positron emission tomography (PET) to observe brain metabolic and dopaminergic changes associated with the addicted state has been particularly useful in identifying core networks that may separately or together underpin the compulsive nature of the condition; these include diminished ventral striatal dopamine D_2 receptor availability (Volkow *et al.* 2008a) associated with either impaired reward sensitivity or inhibitory processes (Volkow *et al.* 2008b).

Addictive disorders exhibit common features among the various substances that have abuse liability, involving alterations in a variety of behaviours and implicating a variety of important basic neuronal systems both in the vulnerability

to addiction and in attainment of the addicted state. The molecular and genetic basis for adaptation within these networks is now yielding to scrutiny (Nestler 2001). This section considers the neuropsychiatric conditions associated with particular addictive drugs, with regard to the addictive processes themselves and the inadvertent toxicity related to consumption of the drug.

Alcohol

Effects of alcohol on the nervous system

Alcohol is remarkable both for its long history and ubiquity of use (Edwards 2000) and for the diverse range of nervous system disorders that it can produce.

- 1 Direct effects: alcohol was previously thought to be a simple depressant of CNS functioning, but is highly dose sensitive in its effects.
- 2 A series of disorders, including fits, hallucinosis and delirium tremens, which are largely due to alcohol withdrawal.
- 3 Associated nutritional defects leading variously to Wernicke’s encephalopathy, Korsakoff’s syndrome, peripheral neuropathy and perhaps cerebellar degeneration.
- 4 Resultant end-stage liver disorder or bone marrow suppression may ensue with their own neuropsychiatric complications.

In addition there is evidence that alcohol and/or its metabolites exert lasting neurotoxic effects, most marked in fetal development but also of relevance in recovery from brain injury. The distinction between these mechanisms cannot be considered absolute for all the syndromes concerned, but in general reaches broad agreement. The direct, nutritional and

withdrawal effects of alcohol are considered in the following sections.

Alcohol intoxication

The effects of alcohol consumption are sensitive to dose (measured as blood alcohol level), timing (rising versus declining phase) and social context. Although alcohol is conventionally cited as a central nervous system (CNS) depressant in a manner analogous to that of anaesthetic agents, a specific molecular target has recently been identified on the γ -aminobutyric acid (GABA)_A receptor (Santhakumar *et al.* 2007) leading to augmentation of GABA neurotransmission, although some detailed controversy remains (Lovinger & Homanics 2007). The fact that this has only been discovered recently relates to the relatively high doses of alcohol needed to exert effects, in contrast to high-affinity conventional drug-receptor interactions. The general augmentation of GABA neurotransmission is associated with early net effects on opioidergic and dopaminergic neurotransmission in the ventral striatal 'reward' pathways (Gianoulakis 2001; Barrett *et al.* 2008). These early effects produce stimulation, usually with subjective exhilaration, excitement and loquacity. Personality factors and environmental factors are important at this stage, lively company leading usually to boisterous cheerfulness, whereas alcohol taken alone may intensify feelings of loneliness and depression. Cultural influences are also clearly important in helping to shape the outward evidence of intoxication (Edwards 1974).

At higher doses there are net depressant effects on widespread cortical networks leading to a reduction of psychological efficiency and motor control, which is often at variance with subjective feelings of superiority and skill. Thinking becomes slowed and superficial, with poverty of associations and impaired judgement and reasoning. Learning and retention become faulty, and remote memory unreliable. Acuity of perception is reduced, attention impaired and distractibility increased. Muscular control is impaired at an early stage and reaction times delayed. Later dysarthria, frank incoordination and ataxia appear.

With more severe intoxication there is progressive loss of restraint, self-control becomes undermined and irregularities of behaviour appear. Emotions of hilarity, sadness or self-pity may gain the upper hand, or there may be marked irritability and hostility. With very high blood levels there is increasing drowsiness, leading finally to coma. In alcoholic coma the breathing is slow and stertorous and the temperature subnormal. The pupils may be contracted or widely dilated and the tendon reflexes weak or absent.

A fairly close relationship exists between the intensity of the effects and the level of alcohol in the blood, measured as blood alcohol concentration (BAC), ranging from early euphoria (BAC 0.03–0.12%), lethargy (BAC 0.09–0.25%), confusion (BAC 0.18–0.3%), stupor (BAC 0.25–0.4%), coma

(BAC 0.35–0.5%) and death (BAC > 0.5%). A concentration of 150–250 mg/dL is usually associated with very obvious signs of intoxication. The legal maximum for drivers in the UK is currently set at 80 mg/dL (17.4 mmol/L), although there are arguments for setting this level considerably lower (Fell & Voas 2006). However, the situation is complex, depending on the rate of rise to a given level and also the length of time that alcohol has been in the body, the so-called Mellanby effect. The Mellanby effect refers to the fact that a quick rise will produce effects at a lower level of blood alcohol than a gradual rise, and for a given rate of rise the effects will be less marked if alcohol has been present at a constant level for some time before. Tolerance within the CNS arises both from central adaptation of neurotransmitter signalling and from peripheral metabolic adaptation.

Alcohol and aggression

Alcohol (and other drug) consumption is renowned for its link with the development of violent and aggressive behaviour (Hoaken & Stewart 2003), via a variety of mechanisms including psychostimulant effects, diminished anxiety and pain perception, and impaired inhibition. These factors relating to alcohol use *per se* are often confounded by use of additional drugs, and in the case of long-term users by withdrawal effects and cerebral damage.

Against this unequivocal background, the terms 'pathological intoxication' and the DSM-IV term 'alcohol idiosyncratic intoxication' are controversial, referring to occasional examples of irrational combative behaviour that may develop abruptly during the course of alcohol intoxication. This reaction is often apocryphally stated to occur after consumption of relatively small amounts of alcohol, but there is relatively little evidence to support this. In extreme examples the condition is said to present as an outburst of uncontrollable rage and excitement leading to destructive actions against other persons and property. This is the 'pathological reaction to alcohol', 'pathological intoxication', 'acute alcoholic paranoid state' or '*manie à potu*' much discussed in the earlier literature. As typically described, the behaviour is out of character for the individual concerned, the duration is short and there is subsequently amnesia for the entire episode. There have been many critical studies relating to the condition or its antecedents. Coid (1979), in a thorough review, found virtually nothing to support the notion that small amounts of alcohol could trigger such outbursts, and little to suggest that they could develop in persons of stable disposition.

Alcoholic 'blackouts'

Special interest attaches to the abnormalities of memory that may follow a period of severe intoxication. An amnesic gap will of course follow any bout of drinking which is carried to the point of severe impairment of consciousness, but the

alcoholic 'blackout' is a phenomenon of a more specific kind. It consists of a dense amnesia for significant events that have occurred during a drinking episode, when at the time outward behaviour perhaps seemed little disordered. Usually the gap extends for a period of several hours, but very occasionally it may cover several days. The subject may have carried on a conversation and gone through quite elaborate activities, for all of which there is no trace of memory next day. On rare occasions grossly abnormal or even criminal conduct may have occurred during the episode, and the amnesic gap can then become a matter of medicolegal importance (Sweeney 1990). The onset, as judged by subjective recall, is usually abrupt, and the end of the amnesic gap may be equally sharp if sleep does not follow directly.

Goodwin *et al.* (1969a,b) presented a detailed description of the nature of blackouts in 64 alcoholic subjects. They confirmed that behaviour during the episode was usually similar to behaviour during any heavy drinking bout, except that some subjects tended to travel long distances as in fugue states. Thus one-quarter of their patients had found themselves in strange places with no recollection of how they got there. The wives of two patients claimed that they could tell when a blackout was in progress on account of a glassy stare, belligerent behaviour or the repetition of questions which showed that experiences were failing to register. En bloc blackouts, as just described, were distinguished from 'fragmentary' losses in which the subject was unaware that events had been forgotten until he was told about them later. Sometimes in this milder variety the memories might return with the passage of time, and sometimes recall was facilitated by further drinking. Thus many subjects had had the experience of hiding money or alcohol when drinking, forgetting it when sober, and later having the memory return in a subsequent drinking bout. The occurrence of blackouts was directly associated with the severity and duration of alcoholism. They appeared only late in the course of the illness, and well after physical dependence and loss of control had become established. Blackouts were very rarely seen unless large amounts of alcohol were being consumed, chiefly in the form of spirits. Goodwin *et al.* also noticed a fairly strong association with a prior history of head injury. Tarter and Schneider (1976) investigated the possibility that alcoholics subject to blackouts might have some enduring impairment of memory when sober, but with negative results. Those with frequent blackouts performed as well as those in whom blackouts were rare on a wide battery of memory measures. The quantity of intake on a given occasion again seemed to be the discriminating factor: the group with many blackouts had a significantly greater tendency to drink to intoxication or until falling asleep, and showed a significantly higher frequency of craving, tolerance and loss of control.

The pathogenesis of these episodes remains uncertain. An interesting suggestion is that they may represent the effects of 'state-dependent learning'. It has been shown that animals

trained in a drugged state may 'remember' their training better when retested in a comparable drugged state, indicating that learning depends for its optimum expression on restoration of the original conditions in which the learning was acquired. Goodwin *et al.* (1969c) have demonstrated an analogous situation in volunteers trained and tested under the effects of alcohol. For some tasks, learning transfer proved to be better when the subject was intoxicated in both the first and the second test sessions than when intoxicated in the first but sober in the second. This accords with the observation cited above that events during an alcoholic blackout may sometimes be recalled under subsequent alcoholic intoxication.

Treatment of intoxication

An acute episode of intoxication rarely calls for specific medical treatment, but severely intoxicated persons should be kept under close observation in case alcoholic coma should supervene. Gastric lavage is usually unnecessary since alcohol is rapidly absorbed from the stomach. However, if there is a possibility that drugs have been taken as well, lavage will be indicated. Episodes of paranoid or combative behaviour may, on occasion, require sedation with major tranquillisers, but there are obvious hazards involved in adding one cerebral depressant to another. In actual management the most important factor is usually the handling that the patient receives from those around, who must attempt to react in as good-natured and unprovocative a way as possible. Kelly *et al.* (1971) have shown that intravenous injections of high-potency vitamins B and C can reduce the subjective effects of intoxication and improve performance on reaction time tests, apparently by virtue of a direct effect on the CNS, but this will rarely need to be exploited in practice. Alcoholic coma represents a medical emergency and should be managed in hospital. Care is needed to exclude coincident head injury and its complications, gastrointestinal bleeding, hepatic failure, pneumonia or meningitis. Blood should be taken to confirm the presence of significant amounts of alcohol and to exclude alcoholic hypoglycaemia. A clear airway must be maintained, analeptic drugs may be indicated, and peripheral circulatory failure may require intravenous fluids, vasopressor drugs and steroids. If glucose-containing fluids are transfused, thiamine must always be given in case Wernicke's encephalopathy should be precipitated. Intravenous fructose or even peritoneal dialysis may occasionally be indicated to accelerate the rate of fall in blood alcohol level (O'Neill *et al.* 1984).

Abstinence or withdrawal syndromes

An important group of manifestations occur against a background of severe alcohol abuse but make their appearance usually after a period of complete or relative abstinence. It seems therefore that they depend not on the direct toxic effects of alcohol present at the time, but rather on a fall in the

level circulating within the body (Victor & Adams 1953; Isbell *et al.* 1955). They include tremulousness, hallucinosis, fits and, most important of all, delirium tremens.

The precise mechanisms underlying these disorders are far from clear. Where hallucinosis and delirium tremens are concerned several complex factors are probably at work. However, all share in common the tendency to occur shortly after drinking has stopped or been abruptly curtailed. Isbell *et al.* (1955) found that the abstinence syndrome, characterised by tremors, weakness, nausea, vomiting, hyperreflexia and fever, was related to the amount of alcohol that had been taken and the duration of consumption. The discovery of the different stages of sleep brought new evidence concerning alcohol withdrawal (Greenberg & Pearlman 1967; Gross & Goodenough 1968). Increasing levels of alcohol suppress the rapid eye movement (REM) phase of sleep (see Chapter 13) and the dreaming associated with it. With continuation of drinking some readjustment occurs, but on withdrawal an abrupt rebound is seen with a great excess of REM sleep. Immediately prior to an attack of delirium tremens, REM sleep may occupy the whole of the sleeping time. It has been suggested that the vivid hallucinations of delirium tremens may represent a 'spilling over' of this active dream material into waking life. The essential mechanisms remain to be clarified, but certainly there appears to be an important relationship between the nature of the sleep disturbances associated with alcohol withdrawal and the clinical manifestations that occur.

Hemmingsen and Kramp (1988) reviewed experimental work indicative of changes in membrane phospholipids and synaptic structure following repeated alcohol withdrawal. They suggested that withdrawal reactions consist essentially of two components: physical signs such as tremor which are determined by the degree of physical dependence developed during the most recent drinking bout; and seizures, hallucinations and delirium that reflect long-term CNS dysfunction accruing over many years of repeated intoxication and withdrawal. A combination of both factors may be operative in some of the withdrawal phenomena encountered.

From clinical evidence it would appear that tremulousness, nausea and transient hallucinations in clear consciousness are among the earliest withdrawal phenomena, occurring often within 3–12 hours of cessation of drinking. Fits occur somewhat later after an interval of 12–48 hours, and the full syndrome of delirium tremens usually only after 3–4 days (Victor & Adams 1953). It is well established that a prolonged period of indulgence is necessary for the more severe effects to occur. With all withdrawal phenomena temporary alleviation follows the taking of alcohol again. All are essentially benign conditions with the exception of delirium tremens.

Alcoholic tremor

This, the commonest withdrawal effect, is usually associated with general weakness, nausea and irritability. In mild form

it can occur after a single night's abstinence and after a period of drinking of only several days. In severe form it usually occurs 12–24 hours after stopping, and only after several weeks of continuous drinking. The patient is alert, startles easily, suffers insomnia and craves the relief which further alcohol will bring. Usually the disorder subsides over several hours or days, but after severe attacks it may be 1 or 2 weeks before the patient is composed and can sleep without sedation.

Hallucinosis

Approximately one-quarter of tremulous patients have disordered sense perception, ranging from transitory misperceptions of familiar objects to illusions and hallucinations (Victor & Adams 1953). Hallucinations usually occur in both the visual and auditory modalities, are generally fleeting, and emerge in clear consciousness. The absence of disorientation, confusion and psychomotor overactivity is important in distinguishing the condition from delirium tremens. It is usually a benign condition, lasting often less than 24 hours and rarely for more than a few days.

Sabot *et al.* (1968) found that the hallucinations are often accompanied by simple auditory and visual sensory disturbances that seem to facilitate their appearance. Tinnitus is common with auditory hallucinations, antedating their appearance and persisting after they have cleared. Visual disturbances in the form of blurring, flashes and spots are usually reported by patients with formed visual hallucinations. The visual hallucinations are mostly of small animals such as rodents and insects, characteristically moving rapidly on the walls, floor or ceiling. Larger animals or human beings may also be seen, or fleeting half-formed images of faces.

As with tremulousness, withdrawal of alcohol appears to be the chief factor leading to transient hallucinations. Occasional patients, however, develop hallucinations while continuing to drink, and in these it has been suggested that thiamine deficiency may be a contributory cause (Morgan 1968). Blackstock *et al.* (1972) followed this possibility further, but were unable to demonstrate a significant difference in indicators of thiamine levels between alcoholics with or without a recent episode of hallucinatory disturbance.

The term *alcoholic hallucinosis* is sometimes used in a more restricted sense to refer to the relatively rare condition in which verbal auditory hallucinations occur alone, again in a setting of clear consciousness. Most examples clear within a few days, but the disorder may sometimes be prolonged. As such the picture may strongly resemble schizophrenia, and a good deal of discussion has centred on its nosological status. The auditory hallucinations often commence as simple sounds such as buzzing, roaring or the ringing of bells. Gradually they take on vocal form, usually the voices of friends or enemies who malign, threaten or reproach the patient. The hallucinations may consist of a single derogatory remark

repeated with relentless persistence, or the patient may be assailed by a combination of accusations and admonitions. He may be discovered arguing angrily with his voices, or he may complain to the police about them. Sometimes the voices command the patient to do things against his will, and their compelling quality may be such that he is driven to a suicide attempt or some episode of bizarre behaviour. Usually the voices address the patient directly, but sometimes they converse with one another about him, referring to him in the third person as in schizophrenia. Secondary delusional interpretations follow upon the hallucinatory experiences, and the patient comes to believe firmly that he is watched, hounded or in danger.

The result is an illness which at first sight resembles acute paranoid schizophrenia. However, the delusions will be found to follow only the hallucinatory experiences and not to arise autochthonously. Schizophrenic thought disorder is not seen, nor incongruity of affect, and insight is regained immediately the voices begin to wane. The syndrome must, of course, be viewed separately from the picture seen in established schizophrenic patients who also drink. Such patients may similarly develop abrupt auditory hallucinations when drinking and during withdrawal, since drinking bouts may aggravate the schizophrenic process. The distinction is made on the basis of the preceding history and the features in the mental state as just outlined.

Victor and Hope (1958) reviewed the divergent views about the implications of the illness, ranging from the belief that it represents a form of schizophrenia released by alcohol to the view that it represents an independent psychosis induced by drinking for many years. Of their 76 examples, 90% showed hallucinations that were benign and transient, the great majority clearing within a week. Hallucinations became chronic in only eight patients, persisting then for months or years. In four of the latter the disorder ultimately resolved without the development of more serious psychiatric illness; only in the remaining four was there progression to a true schizophrenia-like illness with ideas of influence, emotional withdrawal and persistent paranoid delusions. Family histories gave no indication of special allegiance with schizophrenia, and the previous personality tended to be cyclothymic rather than schizoid. This applied even in those rare cases which did prove ultimately to develop a schizophrenia-like illness. There is therefore little to suggest that auditory hallucinosis is merely latent schizophrenia made manifest by alcohol. The mechanisms involved remain uncertain, beyond the fact that prolonged indulgence in alcohol is a necessary precursor and that abstinence is frequently observed prior to its onset. Of the 76 cases reported by Victor and Hope (1958), only 15 began while the patient was still drinking, and three of these were reducing their intake substantially at the time. In the remainder the hallucinations began after drinking had stopped entirely, usually setting in 12–48 hours later. The factors that determine the

occasional prolongation of the hallucinosis or transition to a schizophrenia-like illness remain unknown, but there is some indication that repeated attacks may make the patient ultimately more vulnerable to the type of attack which leads on to schizophrenic deterioration. Neuroleptic drugs are usually effective in treatment.

Withdrawal seizures

The consumption of alcohol can precipitate fits in a person suffering from epilepsy, and sometimes this happens after a 'normal' evening's drinking. Commonly the fit then occurs next morning during sobering up. Quite distinct from this are the withdrawal fits that may occur in persons without special epileptic predisposition. These occur only after heavy consumption, and usually within 12–48 hours of the termination of a long-continued bout. They are usually seen only after several years of established alcohol addiction. Very occasionally they occur while consumption continues, presumably as a result of transient falls in the blood alcohol level.

Mostly the fits occur in bouts of two to six at a time, and very occasionally status epilepticus may be precipitated. The fits are usually grand mal in type. If a focal component exists, this is likely to be the result of trauma in addition to alcoholism. In almost 30% of cases the fits are followed by delirium tremens. Conversely, 30% of cases of delirium tremens and 10% of cases of auditory hallucinosis are preceded by fits (Victor & Adams 1953). Electroencephalography (EEG) is abnormal at the time of the fits, but reverts to normal thereafter. It remains normal in the intervals between, thus discrediting the wide belief that they represent a latent epileptic process that has been brought to light (Victor 1966). Furthermore, in epileptic patients seizures may be closely associated with alcohol intake, sometimes repeatedly and in the absence of other predisposing factors (Brennan & Lyttle 1987).

Delirium tremens

Delirium tremens represents by far the most serious of the alcohol withdrawal phenomena, with a mortality of up to 5%. Some large series of cases have been reported to show a lower mortality, but have probably included many partial and incomplete forms.

Definition. The fully developed syndrome consists of vivid hallucinations, delusions, profound confusion, tremor, agitation, sleeplessness and autonomic overactivity. Defined in this way delirium tremens is relatively uncommon, and was found to represent only 5% of a consecutive series of 266 patients admitted to Boston City Hospital with an obvious complication of alcoholism (Victor & Adams 1953). In contrast, in the same series acute tremulousness occurred in 34%, transient hallucinosis with tremor in 11%, auditory hallucinosis in 2%, fits in 12% and Wernicke–Korsakoff syndrome in 3%.

Before diagnosing delirium tremens, McNichol (1970) required the presence of hallucinations along with at least two of the following: confusion and disorientation, tremulousness, increased psychomotor activity, fearfulness and signs of autonomic disturbance. He recognised three grades in the development of the complete syndrome: first, mental sluggishness with tremor and evidence of residual intoxication; later, emotional lability, agitation, fearfulness, increased psychomotor activity, autonomic disturbance, nightmares and disorientation; and finally the onset of definitive delirium tremens with the appearance of hallucinations. The presence of autonomic hyperactivity (tachycardia, sweating, fever) can be of considerable diagnostic importance in pointing to the condition when the cause of a delirious state is not immediately obvious.

Clinical features. Delirium tremens frequently presents in a dramatic manner and appears to have had an explosive onset. However, when opportunities arise for observation during the evolution of the illness, a prodromal phase is commonly seen. The onset is usually at night, with restlessness, insomnia and fear. The patient startles at the least sound, has vivid nightmares and wakes repeatedly in panic. Transient illusions and hallucinations may occur even at this stage, and typically arouse intense anxiety even though insight may still be largely retained.

As the illness becomes more fully declared, the face is anxious or terror stricken. The patient is tremulous, and if out of bed is usually seen to be ataxic. There is evidence of dehydration, with dry lips, a coated tongue and scanty urine. Restlessness is extreme, with agitated activity by day and night, preventing sleep and leading ultimately to dangerous physical exhaustion. Autonomic disturbance shows in perspiration, flushing or pallor, dilated pupils, a weak rapid pulse and mild pyrexia. Epileptic seizures occur in up to one-third of cases, virtually always preceding the delirium (Victor & Adams 1953).

Illusions and hallucinations occur in great profusion, principally in the visual modality but also auditory and haptic. Spots on the counterpane may be mistaken for insects, and cracks on the ceiling for snakes. Visual hallucinations typically consist of fleeting, recurrent and changeable images that compulsively hold the patient's attention. Rats, snakes and other small animals are said to be typical, and can appear in colourful and vivid forms. They are frequently lilliputian in size, and invested with rapid ceaseless activity. The author has observed a patient who followed intently, and with excited comments, a game of football performed continuously for half an hour by two teams of normal-coloured miniature elephants in a corner of his room. Other hallucinations may be normal in size, such as threatening faces or fantastic scenes depicting terrifying situations. Sometimes the hallucinations are amusing or playful in nature, and recapture some of the bonhomie of the patient and his companions

during drinking spells. The patient's occupation and experience may colour the perceptual disorders, the station master seeing trains rapidly approaching him, or the factory worker seeing his bench before him and going through the motions of his work activities.

Auditory hallucinations are commonly of a threatening or persecutory nature. Vestibular disturbances are frequent, and felt by the patient as rotation of the room or movement of the floor. Insects may be felt to be crawling over the skin, perhaps as an elaboration of paraesthesiae.

A marked feature is the intense reality with which the hallucinatory experiences are imbued, and the strong emotional reactions they produce. Apprehension and fear are typical, but amusement and even jocularity may be seen. Sometimes apprehension and amusement are mixed together in a characteristic and paradoxical manner. As with the hallucinations themselves the affective state is often changeable from one moment to another, though fear or even terror is usually uppermost.

The degree of impairment of consciousness varies widely from case to case and in the same patient from one moment to another. It is rarely profound except in the terminal stages, although the true level may be very hard to judge. Diminished awareness of the environment is coupled with overarousal in a characteristic fashion. The patient appears to be alert and over-responsive, but his responsiveness usually proves to be closely tied to his own internal stimuli; he may startle easily but is otherwise largely unaware and indifferent to what proceeds in the real world around him. Disorientation and confusion are very obvious, but the degree of inattention and distractibility may give the impression that consciousness is more severely impaired than is actually the case. When attention can be held fleetingly it is sometimes possible to show that memory and other intellectual functions are intact to a surprising degree.

Speech is usually slurred and with paraphasic errors. In severe examples it may be incoherent and fragmented. Delusions are secondarily elaborated on the faulty perceptual experiences, but are usually fragmented, transitory and as changeable as the hallucinations. Suggestibility is marked and adds to the frequency with which illusions occur; pressing on the eyeballs may cause the patient to see whatever one tells him he sees, and when presented with a blank piece of paper he may proceed to 'read' it on instruction.

EEG typically shows fast activity in delirium tremens. In this it is in marked contrast to the picture seen in most other forms of delirium, where slowing of the dominant rhythms is the characteristic pattern.

Outcome. The disorder is usually short-lived, lasting less than 3 days in the majority of cases. Very rarely recurrent phases may be seen over a longer period of time. Typically it terminates in a prolonged sleep after which the patient feels fully recovered apart from residual weakness and

exhaustion. In rare cases a prolonged attack of delirium tremens may clear to reveal an amnesic syndrome, when Wernicke's encephalopathy had been present and unnoticed during the acute stage.

Death when it occurs is usually due to cardiovascular collapse, infection, hyperthermia, or self-injury during the phase of intense restlessness. Any infective process, particularly pneumonia, markedly increases the mortality.

Aetiology. The precise pathophysiology is unknown. Cerebral oedema was formerly thought to be responsible but has not been adequately confirmed. A primary disorder of the reticular formation is strongly suggested by the clinical components of profound inattention coupled with alertness, overactivity and insomnia. The remarkable association with disturbance of REM sleep has already been described.

Cerebral blood flow studies have indicated a state of increased CNS excitability during the course of delirium, in keeping with the characteristic fast frequencies seen on EEG. Hemmingsen *et al.* (1988) performed xenon-labelled single-photon emission computed tomography (SPECT) in patients with actual or impending delirium tremens, with repeat examination on recovery. Increased hemispheric blood flow correlated significantly with the presence of visual hallucinations and psychomotor agitation, and decreased when the acute phase subsided.

Withdrawal of alcohol is the factor most clearly incriminated in the aetiology of the condition, and in the majority of cases can be detected in the antecedent history. Premonitory symptoms often set in within a day or two of cessation of drinking, but the full-blown syndrome usually appears only after 3 or 4 days of abstinence. Refeeding with alcohol has been shown to ameliorate the condition. Nevertheless, some cases undoubtedly begin during a bout of heavy consumption, and reduction of intake below some critical value must then be postulated. It can be shown that trauma or infection are present from the outset in up to half of cases, many others having liver failure, gastrointestinal bleeding or hypoglycaemia. Lundquist (1961) found biochemical evidence of acute liver damage in up to 90% of patients with delirium tremens. A multifactorial aetiology will probably prove to be the complete explanation, involving complex metabolic and neurophysiological pathways.

Treatment

Treatment of minor withdrawal symptoms can often be undertaken on an outpatient basis with the help of sedation from chlordiazepoxide. However, patients with a history of withdrawal seizures, and those with any indication of impending delirium tremens, should be admitted to hospital immediately. Management will in essence consist of close nursing observation at regular intervals, so that the dosage of sedative drugs can be titrated against the symptoms displayed. Edwards (1982) recommends chlordiazepoxide up

to 40 mg three or four times daily, starting if necessary with an intramuscular dose of 50–100 mg. Treatment with clome-thiazole (chlormethiazole) is an alternative. The drugs are then gradually tailed off over several days at a rate that prevents significant recrudescence of withdrawal symptoms.

With established delirium tremens, treatment must always be in hospital, preferably in a setting where the medical and nursing staff are experienced with the procedures involved. The necessary steps are described by Rix (1978) and Edwards (1982). Fluid replacement and adequate sedation are the first essentials, with careful examination to detect complicating pathologies which aggravate the delirium and greatly worsen prognosis.

Head injury and infection must always be borne in mind. Skull and chest radiography will be required. Coincident intoxication with sedative drugs may lead to particularly severe withdrawal manifestations. Hypoglycaemia, hepatic failure, uraemia and electrolyte imbalance will need to be excluded. Wernicke's encephalopathy must be detected early and treated vigorously. Cardiac failure, gastroduodenal bleeding or bleeding from oesophageal varices may be present. A close watch must be kept at all stages for seizures or circulatory collapse.

The intensity of treatment required will obviously depend on the severity of delirium that has become established. When the syndrome is well developed, half-hourly recordings of temperature, pulse and blood pressure should be made, along with a record of fluid intake and output. At least 6 L of fluid per day will be required, of which 1.5 L should be given as normal saline. If adequate oral intake cannot be ensured, intravenous administration must be started with 5% glucose solution or glucose in saline. Hypokalaemia is a special risk. Hypomagnesaemia may occur.

Adequate sedation is essential, and the dosage should be monitored closely against the patient's clinical state and level of consciousness. Other treatment must always include high-potency vitamin preparations as prophylaxis against Wernicke's encephalopathy or nicotinic acid deficiency encephalopathy. Anticonvulsant medication should be given routinely when there is a past history of withdrawal seizures. Cardiovascular collapse, vomiting or hyperthermia will require appropriate management.

Alcoholic cognitive impairment and cerebral atrophy

The conception of 'alcoholic dementia' has had a chequered history, figuring prominently in early textbooks of psychiatry but later yielding pride of place to Korsakoff's syndrome (Lishman 1981). Nowadays the idea of a genuine dementia caused by alcohol is quite commonly viewed with caution. Many patients labelled as having as alcoholic dementia are indeed suffering from Korsakoff's syndrome (though it seems possible that the reverse also obtains, as described under Korsakoff's syndrome, later in chapter. Others are merely displaying profound social disorganisation in the

context of chronic continuing inebriation. When opportunities arise to assess the latter after a period of total abstinence, intellectual functions may turn out to be substantially intact. Other alcoholics are suffering essentially from a coincident vascular dementia, the effects of multiple head injuries or a dementia of the Alzheimer type.

Nevertheless, clinical experience suggests that the long-continued abuse of alcohol may sometimes lead directly to severe cognitive impairment. Alcohol is suspected of being at least a contributory cause in a substantial number of demented patients seen in hospital, approximately 10% in historical series. Moreover, for every patient who has reached the stage of being investigated for a possible dementia, many others may be suffering from milder, and perhaps protracted, earlier stages of such disorder. Adequate epidemiological studies are not available to clarify the problem directly. Only a proportion of alcoholics come before treatment services, and a comprehensive follow-up of those who do can present formidable problems. Furthermore, it is possible that those who suffer marked cognitive impairment are particularly liable to be lost to view as time goes by. There have been few surveys of 'skid row' alcoholics who may be expected to represent the more deteriorated subjects.

Psychological evidence

Clinical psychologists have presented a now substantial body of evidence which shows that severe alcoholics, even after thorough 'drying out', remain compromised on a broad range of psychological functions. These extend well beyond memory deficits alone to include problems with visuospatial competence, abstracting ability and complex reasoning. Such deficits can be demonstrated even when verbal ability is well preserved, which of course can produce a misleading impression at interview. Again it is noteworthy that they have emerged in subjects presenting themselves for treatment; the cognitive status of those out of contact with medical services has for obvious reasons not been determined.

Psychological assessments during the first few weeks of abstinence show substantial recovery of intellectual and memory functions, so assessment of the stable cognitive state must be deferred for some considerable time. Continuing restitution of function may indeed proceed for a period of several months. Nevertheless, it seems that even after a year of abstinence psychological deficits persist on tests of psychomotor speed, perceptual-motor functioning and visuospatial competence, also measures of abstracting ability and reasoning. Careful tests of memory function can likewise remain impaired, to the extent that a continuum of memory impairment has been postulated, ranging from normality at one extreme to the fully-fledged picture of the Korsakoff amnesic defect at the other (Ryback 1971; Ryan & Butters 1980). New learning capacity has been found to remain impaired after a minimum of 5 years' abstinence, likewise capacity for complex figure-ground analysis

(Brandt *et al.* 1983). Deficits on tests related to frontal lobe function, such as the Wisconsin Card Sorting Test, are particularly noteworthy. Frontal dysfunction could be relevant to aspects of the personality change encountered in alcoholics – the circumstantiality, plausibility and weakness of volition – that may contribute significantly to relapse. A vicious circle may often be established, with worsening cognitive status contributing to the potentiation of the addiction.

Jacobson and Lishman (1987) showed variable degrees of cognitive impairment in Korsakoff and non-Korsakoff alcoholics, and Acker (1985) showed that women were particularly vulnerable to such impairments. More recently, Oscar-Berman and Marinkovic (2003) have documented the cognitive and neurobiological changes in chronic alcoholics, particularly in cognitive functions dependent on the frontal lobes. Sullivan *et al.* (2000a, 2002) have described impairments on tasks such as delayed recall, visuospatial function, and attention; in women, visuospatial function and verbal and nonverbal working memory were particularly affected. This group has also examined changes with abstinence, finding that abstainers improve more than alcoholics who initially abstain but who then return to drinking on aspects of general memory as well as ataxia (Rosenbloom *et al.* 2007). As a heavy drinker gets older, the brain damage occasioned by alcoholism will couple with other pathologies – those of ageing, trauma, vascular changes and hepatic dysfunction – leading to more serious and irreversible change.

Neuropathology

Direct appraisal of cerebral pathology in alcoholics, over and above that concerned with the classic Wernicke lesion, has met with conflicting findings. Cerebral atrophy, mild or moderate in degree, was reported in a high proportion of Courville's (1955) chronic alcoholics at post-mortem, as well as in half of Neuberger's (1957) and all of Lynch's (1960). However, other reports do not find it or do not comment upon it. On microscopy Courville found arachnoidal thickening and cell degeneration and loss, affecting mainly the smaller pyramidal cells of the superficial and intermediate laminae. Disintegration of nerve fibres was also observed. Lynch (1960) described a similar histological picture in 11 chronic alcoholics with adequate nutritional status, when compared with a group of non-alcoholic subjects of the same age and sex. Commenting on the negative reports in the literature, he attributed this to a waning of neuropathological interest in the cortex of alcoholics, with the accent of pathological enquiry centring increasingly on the Wernicke lesion at the base of the brain and on changes in the cerebellum. He also stressed how difficult it is to chart changes, degenerations and loss in such a complex and crowded area as the cortex.

Quantitative studies on brains obtained at post-mortem have confirmed that atrophy or 'shrinkage' is indeed often detectable. Thus in comparison with controls brain weight is slightly but significantly

reduced in the alcoholic (Harper & Blumberg 1982; Torvik *et al.* 1982), and the pericerebral space over the cortex is enlarged (Harper & Kril 1985). This emerges whether or not there is evidence of nutritional brain damage, perhaps pointing to the role of alcohol neurotoxicity. The amount of white matter in the cerebral hemispheres is reduced, and the ventricles enlarged by over one-third, a figure not dissimilar from that found in computed tomography (CT) studies as discussed below (Harper *et al.* 1985; de la Monte 1988). The thickness of the corpus callosum is also significantly reduced by approximately 20% (Harper & Kril 1988).

Lishman (1986, 1990) suggested that the Wernicke–Korsakoff lesion (see below) may sometimes itself be responsible for pictures of dementia by encroaching on key neurochemical nuclei at the base of the brain, with consequent disruption of monoaminergic and cholinergic inputs to the cortex. Pursuing this hypothesis further it is possible to amass evidence that the basal regions of the brain are vulnerable not only to thiamine lack but also to the direct toxic action of alcohol (Lishman 1990). A dual system of this nature could also explain the spectrum of cognitive changes encountered in patients labelled as suffering from Korsakoff’s syndrome, ranging from circumscribed memory deficits to more global impairment in a proportion of cases.

Laboratory evidence lends support to the possibility that a direct toxic action of alcohol on the brain may play a considerable role. Leonard (1986) and Charness *et al.* (1989) review its effects on neuronal membranes, cell transport systems and neurotransmitter functions. Studies in mice and rats have shown that brain changes can be induced after a period of several months on a diet supplemented with alcohol (Riley & Walker 1978; Walker *et al.* 1980a,b). Marked alterations in dendritic morphology were found in the hippocampal pyramidal neurones, dentate granular layers and cerebellar vermis, proceeding to cell degeneration and loss. These effects were produced despite the maintenance of good nutrition in all other respects. Detailed cell counts have indicated a 22% reduction in the number of neurones in the superior frontal cortex, along with reduction in the size of neurones in the motor and cingulate cortices (Harper *et al.* 1987; Kril & Harper 1989). Other cortical areas seem not to have been extensively examined. A quantitative study of the extent of dendritic arborisations in layer III pyramidal neurones from the frontal and motor cortex has shown significant reductions in mean dendritic length, number of branches and mean width of basal dendritic fields (Harper & Corbett 1990). Moreover, West *et al.* (1982) showed that alcohol inhibits the reactive sprouting of dendrites in the rat hippocampus that constitutes the normal response to injury. McMullen *et al.* (1984) found that ingestion of alcohol by well-nourished rats leads to reduction of branching in dendritic domains, and a reduction of thickness in corresponding dendritic strata. Abstinence then allows regrowth of dendritic branching and a return to normal thickness of the strata. King *et al.* (1988) have shown similar reversible alterations in the density of dendritic spines in the rat hippocampus. The plasticity inherent in the adult brain with regard to den-

dritic growth and sprouting (Buell & Coleman 1979, 1981; Flood & Coleman 1986) suggests that continuing growth of the dendritic domains compensates for an age-related decline in neuronal numbers. Dendritic growth may stand to be compromised in the alcoholic subject, with a return to normal levels when prolonged abstinence has been assured. Other factors may also be involved, such as changes in protein or lipid synthesis (Harper 1989; Harper & Kril 1990).

Neuroimaging

Computed tomography and magnetic resonance imaging (MRI) scanning have been conducted on large populations of alcoholics (Ron *et al.* 1982; Lishman *et al.* 1987; Pfefferbaum *et al.* 1995, 2006; Sullivan *et al.* 2000). Compared with normal controls, representative samples of alcoholics have been found commonly to have dilatation of the sulci, fissures and ventricles.

The conclusions to be drawn from these studies are as follows. Some 50–70% of severe chronic alcoholics show indubitable evidence of cortical shrinkage or ventricular dilatation or both. Involvement of the frontal lobes of the brain has sometimes been particularly evident. The changes can be found in quite young alcoholics, appearing well within the first decade of alcohol abuse, although they become more marked in the older age groups studied. Planimetric measures of lateral ventricular size show on average some 50% enlargement compared with age-matched controls. This has emerged even in identical twins discordant for a history of alcoholism (Gurling *et al.* 1984). Atrophy of the cerebellar vermis can also be seen in a high proportion of subjects. However, personal susceptibility to such developments appears to vary widely, in that approximately one-third of subjects continue to show normal scans despite long-continued and severe drinking histories. There are indications that the female brain may be more vulnerable than the male to the development of such CT changes (Jacobson 1986).

MRI has confirmed the ventricular enlargement and the increase in cerebrospinal fluid (CSF) over the cortical surface that is apparent on CT. In Jernigan *et al.*’s (1991a) MRI study, the cortical changes were particularly impressive, and were associated with significant reductions in grey matter in medial temporal, superior frontal and parietal regions. Subcortical grey matter was also reduced, particularly in the caudate nucleus and diencephalon. Sullivan *et al.* (2000a) and Pfefferbaum *et al.* (1995) emphasised the importance of changes in the volume of the third ventricle in non-Korsakoff alcoholics. Jacobson and Lishman (1987) and Oscar-Berman and Marinkovic (2003) have documented the particular vulnerability of the frontal lobes, Sullivan *et al.* (2000b) documented changes in cerebellar volume in relation to ataxia, and Pfefferbaum *et al.* (2006) documented white matter degradation on diffusion tensor imaging.

These cerebral changes clearly antedate clinical evidence of mental impairment, being demonstrable after excluding patients with clinically obvious cognitive deficits. They often appear to set in early during the alcoholic career, and after developing to a certain degree it is possible that they fail to progress further. In seeking clinical associations of the CT findings, few have emerged other than age and duration of abstinence. The duration and severity of alcohol abuse appear to bear little relation to the severity of the cerebral changes once age has been taken into account, although there is some indirect evidence that episodic drinking may be less harmful in this respect than steady continuous drinking.

The most decisive influence, where the drinking history is concerned, has proved to lie with the duration of abstinence. It has been shown that with increasing length of abstinence prior to scanning the CT changes become less pronounced; follow-up over an interval of 1–3 years has confirmed that abstinence in the interim is the factor most closely associated with whether the scans will show improvement (Ron *et al.* 1982; Ron 1983). Even after several years of abstinence, however, as in samples recruited from Alcoholics Anonymous, some degree of persistent ventricular enlargement appears to remain (Jacobson 1986; Lishman *et al.* 1987).

Studies using MRI, which allows more accurate measurement of CSF volumes, have confirmed significant decreases in both ventricular size and subarachnoid spaces during the early weeks of abstinence (Schroth *et al.* 1988). Coincident measurement of T2 values for white matter have served to discount dehydration and rehydration of the brain as the sole explanation; other effects such as increased protein synthesis or increased dendritic growth after withdrawal from alcohol may be more important factors. Pfefferbaum *et al.* (1995, 2006) have also documented changes on MRI following abstinence which suggest that improvement in cortical grey matter, sulcal, and lateral ventricular volumes occurs early in the course of abstinence, with improvement in third ventricular volume appearing later; improvement in white matter microstructural integrity also occurs. This partial reversibility with abstinence is, of course, strong evidence against the possibility that the cerebral changes revealed on the scan may have antedated, and predisposed to, the onset of the alcoholism.

Psychometric testing carried out in conjunction with scanning has indicated, as expected, that a considerable proportion of the alcoholics score poorly on many tests. However, the concordance between measures of functional and structural change has often proved to be low. Bergman *et al.* (1980a,b) found some evidence that impairment of memory and general intelligence was associated with the degree of ventricular enlargement, and that the Halstead Impairment Index was associated with cortical status. However, all such correlations were low. Acker *et al.* (1984) found remarkably few associations on an extensive battery of tests once care had been taken to control for age and estimates of premorbid

intellectual competence. However, on CT studies, Acker *et al.* (1987) found that performance on a battery of memory tests was significantly related to the width of the third ventricle in a group of detoxified non-Korsakoff alcoholics. Not dissimilarly, Jacobson and Lishman (1987) divided a sample of non-Korsakoff alcoholics into those with good and poor memory, according to performance on the Logical Memory Test, and compared their scans with those of Korsakoff patients and normal controls. Both the lateral and the third ventricles tended to be larger in alcoholics with poor rather than good memory, the values in the former approaching the values found in Korsakoff patients and the latter the values found in normal controls. The difference in third ventricular size was statistically significant. In general, the findings suggest that cerebral shrinkage *per se* is a poor marker of functional competence, and that only limited reliance can be placed on scan appearances in evaluating the competence of the individual alcoholic patient, but that some more specific correlations between function and focal neuroimaging change can be obtained.

Wernicke's encephalopathy

Wernicke's encephalopathy represents the acute neuropsychiatric reaction to severe thiamine deficiency. It may be defined as a disorder of acute onset characterised by nystagmus, abducens and conjugate gaze palsies, ataxia of gait, and a global confusional state, occurring together or in various combinations (Victor *et al.* 1971). Wernicke first described the condition in 1881 under the title 'polioencephalitis haemorrhagica superior', reporting two cases in chronic alcoholics and one in a patient with persistent vomiting after sulphuric acid poisoning. Initially it was ascribed to an inflammatory process in the CNS, but abundant evidence has since accumulated to show the role of thiamine deficiency. Alexander (1940) was able to demonstrate lesions in the brains of thiamine-deficient pigeons that were similar in distribution and type to those of Wernicke's encephalopathy, and Jolliffe *et al.* (1941) clearly established the efficacy of thiamine in relieving the ophthalmoplegias and in improving clouding of consciousness in human subjects. Nicotinic acid, in contrast, failed to do so.

Wernicke's encephalopathy and alcoholism

Alcoholism is an important but not exclusive cause of the disorder. It leads to thiamine deficiency by several routes: the replacement of vitamin-containing foods by alcohol, impaired absorption of thiamine from the gut, impairment of storage by the liver, decreased phosphorylation to thiamine pyrophosphate (TPP), and excessive requirements for the metabolism of alcohol. Among alcoholics, partial gastrectomy appears to be a significant additional risk factor (Price & Kerr 1985). However, Wernicke's encephalopathy is known to occur in a number of other conditions all closely
